A variety of ablation techniques are now used to target malignant neoplasms. Percutaneous injection of alcohol (95%) or phenol (6%) is used to target tumors. Alcohol can be instilled using needles or catheters, but the injection is usually quite painful. Large volumes of alcohol or inadvertent injection into a vascular structure can cause tachycardia and respiratory depression. These techniques are older and not as frequently used. More popular ablation techniques involve the use of radiofrequency ablation, cryoablation, and microwaves. These procedures may be lengthy because they involve precise placement of applicators for the delivery of the ablation tool, whatever that may be. Reproducible breath-holds may be needed to facilitate placement. Radiofrequency ablation induces coagulative necrosis at temperatures above 50°C; the heating process can produce pain, whereas cryoablation is a less painful procedure.[62,63] As stated previously, postablation syndrome can occur and is characterized by fever, malaise, nausea, vomiting, and right upper quadrant pain. Dexamethasone may be helpful in prophylaxis. Regional techniques can be used for primary anesthetic and for postprocedural pain.[64]

Computed Tomography–Guided Injections for Pain Management

Procedures for pain management include phenol and alcohol injections into a plexus, ganglion, or nerve. Neurolysis is the intended outcome. Injection of steroids into joints for local pain management and mitigation of inflammatory processes is also performed. Many patients requiring these procedures are tolerant to pain medication. Body habitus may be an important factor in these patients as well, and depending on the source of pain, patients with cancer may be especially challenging in terms of attendant comorbidities. Most often these are palliative procedures. Discussion frequently revolves around addressing advanced directives prior to start of anesthesia.

POSITRON EMISSION TOMOGRAPHY AND POSITRON EMISSION TOMOGRAPHY COMPUTED TOMOGRAPHY

PET is an imaging technique used for diagnosis, staging, and follow-up of malignancies. Scanning is undertaken after injection of a radiolabeled glucose analogue fluorodeoxyglucose (18F-FDG), which is taken up by malignant cells preferentially and is not metabolized, thereby serving as a tumor marker. FDG-PET is used to distinguish benign from malignant lesions, identify metabolically active portions of necrotic tumors, and monitor responses to treatment. The combination of PET/CT provides both the metabolic information of PET and the anatomic precision of CT. PET/CT-guided intervention is an emerging modality.[65] For these procedures, patients are imaged beginning 60 minutes after injection. Imaging may require serial positioning, during which PET and CT images are acquired sequentially, so care must be taken to maintain consistent patient positioning throughout the image acquisition so that misregistration of image overlap does not occur. PET scanners include a long, mobile gantry that both limits access to the patient and requires that monitoring equipment be long enough to accommodate motion of the table.

Hence, PET/CT suites represent another potentially challenging anesthetizing location. Whenever possible, anesthesiologists should be involved in the planning of these suites because wall-mounted gases, suction, and installed monitoring equipment must be strategically placed. It is likely in the future that PET will be used to augment CT-guided interventions; therefore, planning a space that will allow inclusion of anesthesiology equipment will ensure uneventful interventions and optimal outcomes.

MAGNETIC RESONANCE–GUIDED INTERVENTIONS

MRI is an ionizing radiation-free technique that uses magnetic fields and radio waves to create images. The quality of soft tissue images generated by MRI surpasses that of ultrasound or CT. MRI is still largely a diagnostic tool but is emerging as an interventional modality as well. Because MRI can acquire multiplanar, temperature-sensitive, and contrast-enhanced images, complete visualization of interventional implements such as wires or needles is possible.[58] Image quality is proportional to magnet strength. Field strength, measured in Tesla units, ranges from low (0.1-0.5 T), medium (0.5-1.0 T), high (1.5-3.0 T), and ultrahigh (>3.0 T). Imaging sequences can be manipulated to highlight tissue characteristics based on water content, vascularity, and presence of hemosiderin. The superiority of MRI-generated soft tissue images facilitates biopsy and ablation of structures that evade CT or ultrasound.[59]

Physical Constraints of Magnetic Resonance Imaging Suites

All equipment used in the MRI suite must be MRI compatible meaning that the equipment will not cause harm to the patient, affect image quality, or be affected by the MRI scanner. Objects containing iron or stainless steel become mobile projectiles in an MRI suite because of the magnetic field regardless of their size. Therefore, special care must be taken to ensure that all equipment used in an MRI suite is unaffected by magnetic attractive forces, heating, or current induction. Similarly, patients themselves must be screened. Any implanted devices must be assessed for MRI compatibility. Patients with pacemakers, implantable cardioverter-defibrillators (ICDs) (see also Chapter 38), cochlear implants, pumps, nerve stimulators, or other metal objects such as aneurysm clips, metal fragments, or bullets, should not be scanned. These objects are subject to heating and movement. Increasingly, vascular clips, staples, orthopedic implants, heart valves, pacemakers, and other prostheses are non-ferromagnetic and scanning of patients with these implants is possible. Monitoring devices are increasingly available in MRI-compatible format, as are interventional equipment, surgical equipment, and anesthesia equipment.[66] Detailed information regarding MRI safety is available in Chapter 89 and elsewhere.

Claustrophobic or large patients may be unable to tolerate being inside of an MRI machine, making even diagnostic procedures difficult for them. Newer MRIs combine a wider bore with high-field systems, improving accessibility and making it easier for patients to tolerate procedures. Because interventional MRI requires constant movement in and out of the scanner, typical interventions take much longer than the same procedures done elsewhere. Emergencies must be planned for because the MRI interventional suite may be isolated, and conventional emergency equipment may not be MRI compatible. Even a standard laryngoscope can become a deadly missile in an MRI suite.

Magnetic Resonance Imaging–Guided Interventions

In cases in which CT is inadequate, MRI may be useful because of its multiplanar capability. MRI has been used to guide breast and prostate biopsies and biopsies of other tumors not well visualized by other means. For the most part, local anesthesia and sedation suffice for these procedures. Tumor ablation using cryoablative technology can be performed in the MRI suite. This procedure can be done with ultrasound or CT as well, and the choice of MRI as an imaging modality indicates the need for precise soft tissue imaging. MRI also provides better visualization of tissue during freezing and thawing than CT or ultrasound, and MRI-guided cryoablation is safe and effective for liver, kidney, breast, and prostate tumors and in the treatment of uterine fibroids.[67] For these cases, repeated breath-holds may be needed, and the procedures may be lengthy. Pain is not uncommon during freezing and heating of tissues; therefore, general anesthesia may be required.

Bleeding is the most common complication after some of these procedures (also see Chapter 50). Thrombocytopenia is a rare but serious complication of extensive liver ablation. Extensive ablations can also induce myoglobinemia or myoglobinuria. Cryoablation of adrenal lesions can induce hypertensive crises as normal adrenal tissue responds to thawing.[68] MRI can facilitate the use of focused high-intensity ultrasound therapy by providing more precise imaging. Clinical trials of this technique are in progress. Temperature-sensitive MRI images can assess dosage of ultrasound and gadolinium-enhanced MRI images can assess tissue response. MRI offers many potential advantages that may broaden the scope of current interventional procedures because of its capacity to provide improved imaging over that available with CT or ultrasound. The need to develop MRI-safe environments, equipment, and monitoring and to understand the limitations of sedation and need for anesthesia during long and uncomfortable procedures are the next steps in extending the usage of this modality.

Image-Guided Procedures for Specialty Areas: Neuroradiology and Interventional Cardiology

Neuroradiology and interventional cardiology are considered here as specialties because they each mirror areas that anesthesiologists have also chosen to designate as areas of specialization or fellowship training (neuroanesthesia and cardiac anesthesiology) (see also Chapter 57). The language of neurology, neuroradiology, cardiology, and interventional cardiology is part of the language of neuroanesthesia and cardiac anesthesia. Thus, a platform for clear communication exists and should be used to optimize procedural outcome. Of course, as mentioned earlier in this chapter, common vocabulary is necessary but not sufficient; mutual respect, a culture of safety and learning, and a functional teamwork structure are important elements of a successful unit.

Advances in neuroradiology and interventional cardiology have been incredibly rapid—technology has developed and target patient populations have broadened. In both these areas, percutaneous approaches to formerly surgical problems have multiplied, as has the potential for the involvement of anesthesiologists. In many ways, the development of new techniques represents a "disruptive technology"[69] within the field of medicine that promises to further blur distinctions between medical and surgical treatments. The unpredictable and demanding new landscape of novel interventional cases is the future of the practice and the success of these new, cutting-edge interventions relies on our adaptability.

Procedures in the Neuroradiology Suite

The field of interventional neuroradiology has grown broadly and rapidly as a result of technological advances in devices (catheters, coils, and stents), improved imaging techniques, and safer contrast media (see also Chapter 57). Cerebral angiography remains the gold standard for imaging the cerebral vasculature. Diagnostic cerebral angiography usually can be performed with conscious sedation while interventional procedures require a broad range of anesthesiology care due to the complexity of the techniques, need for a still patient, and long procedure duration. Certain procedures generate hemodynamic perturbations that require management by the anesthesiologist. On the other hand, some procedures (i.e., carotid stenting) can be done with the patient awake, to facilitate neurologic assessment. Anesthesia for each of these procedures must be considered in concert with patient comorbidities and status on a case-by-case basis. Although the technical details of neuroradiology procedures are beyond the scope of this chapter (see Chapter 57), the basic focus and required steps in commonly performed interventions are outlined here.

GENERAL CONSIDERATIONS FOR ANESTHESIOLOGISTS IN THE INTERVENTIONAL SUITE

As with other areas outside of the OR, physical characteristics of the interventional suite affect the practice of anesthesia (see also Chapter 39). Equipment makes access to the patient's head difficult and radiation exposure must be considered as these procedures emit large amounts of radiation due to bi-plane imaging techniques. In addition, contrast reactions must be anticipated. Because of the intricacy of the procedures, uncooperative patients and those with impaired consciousness or movement disorders should be considered candidates for general anesthesia. If time permits, arterial lines are advisable; if not, the neurointerventionalist can upsize a femoral sheath to permit arterial monitoring. Other neuromonitoring technologies can be helpful as indirect measures of cerebral perfusion; electroencephalography and somatosensory, motor, and brainstem evoked potentials have all been studied in this regard. Many neuroanesthesiologists use opioids, avoiding inhalational agents because of their confounding effects on electroencephalography and evoked potentials. As in the OR and other non-OR sites, the anesthesiologist and proceduralist need to be aware of each other's plan, progress, and complications.

ENDOVASCULAR TREATMENT OF CEREBRAL ANEURYSMS

Endovascular treatment of cerebral aneurysms achieves percutaneous isolation of aneurysms from the circulation by placement of a soft platinum coil within the aneurysm (see also Chapter 57. Intraaneurysmal embolization may require the placement of several coils. Coiling procedures are least complex in aneurysms with a small, narrow neck. Coiling of wide-necked aneurysms requires the introduction of a stent with the coil subsequently introduced through the stent.[51] Stent implantation, which requires preprocedure and postprocedure anticoagulation, increases bleeding risk; therefore, stent-assisted coil embolization is limited to unruptured aneurysms. Endovascular treatment with coils demonstrated better outcomes than surgical clipping in patients who sustained a subarachnoid hemorrhage related to an aneurysm, but clipping improved resolution of cranial neuropathies.[70]

Complications include aneurysm rupture or thromboembolism. If rupture occurs, heparin should be reversed with protamine (1 mg/100 IU heparin) and the arterial blood pressure decreased by the anesthesiologist. The usual course of action is to continue the coiling as quickly as possible. Thromboembolic events, usually platelet related, occur in 3% of cases and cause permanent neurologic deficit in 1.7% to 5% of cases [71] (see also Chapter 50). If a thromboembolic event occurs, the proceduralist will make an attempt to dissolve or remove the clot with either a mechanical device or the intraarterial administration of a thrombolytic or antiplatelet agent.

Some aneurysms have no neck or are inaccessible. This is the case most commonly with cavernous, petrous, extracranial vertebral, internal carotid, or giant aneurysms of the subarachnoid space. Treatment of these aneurysms requires parent artery occlusion, which is possible only if good collateral flow exists. This requires a preliminary procedure known as a parent artery balloon test occlusion.[72] It involves first advancing a wire to the site of the proposed artery sacrifice. A neurologic examination is then performed, heparin is administered to prolong the activated clotting time, and a balloon is inflated to occlude the artery. Neurologic examination follows. In some institutions radionuclide enhanced cerebral vascular studies are undertaken. If the patient tolerates occlusion, coiling may proceed. If not, a surgical intracranial bypass may be required.

ENDOVASCULAR TREATMENT OF ARTERIOVENOUS MALFORMATIONS

AVMs in the brain are an area of direct connection between small arteries and the venous system without normally intervening capillaries. The usual presentation of this lesion is intracranial hemorrhage. Patients with AVM must be angiographically evaluated for the presence of associated aneurysms. This evaluation involves catheterization of selective feeder arteries to determine the precise source of the hemorrhage. Current therapy for cerebral AVM includes embolization, microsurgical resection, stereotactic radiosurgery, or combination treatment. Embolization preceding surgery can minimize bleeding and reduce AVM size. Small AVMs may be appropriate for endovascular treatment. Techniques for embolization of AVMs in the neuroradiology suite include the use of flow-directed microcatheters, solid occlusive devices, particulates, and liquid embolic agents. Complications include embolization of post-AVM vessels precipitating rupture, passage of embolic material into the pulmonary circulation, and microcatheter entrapment.[73]

Interventional Neuroradiology: Acute Stroke Treatments

Acute embolic stroke treatment has evolved significantly over the last 10 years. Intravenous r-tPA treatment has been supplemented with intraarterial thrombolysis as it allows extension of the treatment time window from 3 to 6 hours, delivers a higher concentration of lytic drug to the target vessel, yields higher recanalization rates, and can be combined with other interventional techniques.

Initially, a detailed cerebral angiogram is obtained and the level of occlusion is identified. A microcatheter is inserted over a microguidewire, contrast is injected, and the clot is localized. At this point, r-tPA is injected beyond the clot and the catheter is pulled back through the thrombus. If the occlusion persists, mechanical means of clot disruption or extraction are considered. This must be undertaken within 8 hours of the event. Several devices are available for retrieval or aspiration. Stent placement or angioplasty is also possible. A recent study of thrombectomy in patients treated within 8 hours demonstrated a recanalization rate of 57.3% of treatable vessels and 69.5% after adjunctive therapy. Thirty-nine percent of patients had favorable outcomes.[74] The therapeutic window available for interventions is 6 hours after the patient was last seen as normal for intraarterial thrombolysis and 8 hours for mechanical clot disruption. The recently published DAWN trial showed that the time window for endovascular thrombectomy may be extended to 24 hours with certain selection criteria.[75]

Patients presenting with acute stroke can range in presentation from relatively stable to severely compromised. Often the anesthesia team has little time to gather preoperative information. Evidence from studies suggests that anesthetic choice may have an impact on neurological outcomes. General anesthesia may provide comfort and an immobile patient; however, it can also prolong time to treatment and produce unfavorable hemodynamic perturbations. Monitored anesthesia care, on the other hand, allows for quicker intervention and fewer hemodynamic swings; however, patients may be uncooperative and at risk of aspiration as the airway is not protected. To date there are no randomized controlled trials, but retrospective studies suggest that sedation may offer improved neurological outcomes.[76] Anesthetic choice should first and foremost be guided by the patient's condition and tailored to each individual situation.

Invasive blood pressure monitoring is preferable and can be obtained after the procedure is started as long as it does not delay time to treatment. If intracranial pressure is an issue, a bolt or extraventricular drain may be necessary to measure intracranial pressure during the procedure.

Interventional Cardiology Procedures: General Considerations for the Electrophysiology and Catheterization Laboratories

For the past 20 years, medicine has witnessed a crescendo of new procedures in electrophysiology and interventional cardiology. In parallel, the need for anesthesiology involvement has increased. For instance, the electrophysiology laboratory now offers expanded treatment options for patients with late-stage heart failure and complex arrhythmias. Because many of these procedures are long and involved, most are performed with general anesthesia or a combination of sedation and general anesthesia. Similarly, percutaneous treatment of structural heart disease has become part of the repertoire of interventional cardiologists creating new and exciting opportunities for cardiac anesthesiologists. The opportunity to provide real-time echocardiographic guidance represents a new horizon for cardiac anesthesiologists who can now care for structural heart disease patients as co-proceduralists (further discussed in the addendum to this chapter).

Many patients in both the electrophysiology and catheterization laboratories have significant comorbidities. The proceduralists involved may be unaware of the ramifications for procedural success. In this new and challenging arena, collaboration and planning between interventionalist and anesthesiologist are required to ensure patient safety and optimize outcome. A clear understanding of the procedure to be performed, possible pitfalls, and unique patient characteristics is necessary for the formulation of a safe and effective plan. As always, a common knowledge base and vocabulary facilitate integration of care.

THE ELECTROPHYSIOLOGY LABORATORY ENVIRONMENT: UNIQUE CHALLENGES FOR ANESTHESIOLOGISTS

This section presents an overview of electrophysiology laboratory environments, the evolution and future pathways of current practices, cases performed in each venue, and current anesthetic approaches. Common electrophysiology laboratory procedures include the following (see also Chapter 38):

1. Electrophysiology studies
2. Atrial and ventricular ablation procedures
3. Implantation and removal of cardioverter-defibrillator and pacing devices

Invasive cardiology procedures performed in the cardiac catheterization laboratory include the following:

1. Diagnostic cardiac catheterizations and coronary interventions
2. Peripheral vascular diagnostic and therapeutic procedures
3. Implantation of intraaortic balloon pumps (IABPs) and percutaneous left ventricular assist devices
4. Amelioration of structural heart disease by the placement of intracardiac devices

These procedures potentially require the involvement of anesthesiologists if the patient has significant comorbidities. However, some ablations and electrophysiology studies and some device implants and removals can be performed with nurse-administered sedation. Some procedures are lengthy and technically demanding and require that the patient be still; in such situations, preservation of hemodynamic stability and need for a motionless field may indicate the need for a general anesthetic.

The electrophysiology and catheterization laboratory environments differ significantly from the OR. It is important for anesthesiologists to recognize the limitations of the venue and understand the flow of cases and responsibilities of ancillary personnel. Innovation and flexibility are necessary with respect to equipment availability and positioning, and the nature and tempo of the anesthesiology-cardiology interface.

Room Configuration and Equipment Layout

Electrophysiology and catheterization laboratories are built with separate control stations and procedure rooms. The control area is shielded from radiation and is the vantage point from which the progress of the procedure can be recorded. An operator may record procedural and patient monitoring data as well as video and audio information. The operator may also engage in digital record keeping. The ability to manipulate anesthetic equipment is typically not included in the array of controls in the station.

Within the procedure room itself, cardiologists, anesthesiologists, nurses, and radiology technicians contribute to the care of the patient during the procedure. It can be daunting to know who is who and who is responsible for what; thus, it is best to ask if unsure. In an emergency, understanding who is in charge of a life-saving therapy (i.e., the defibrillator) can eliminate confusion and save lives.

The procedure room includes fluoroscopy equipment (x-ray tube and C-arm), which usually surrounds the patient's head making access difficult. The procedure table is mobile and screens for viewing the procedure are typically at 90 degrees to the anesthesiologist. Sterile tables for the cardiologist, closets or portable storage units for various catheters and wires for the procedures, and blood analysis machines may take up a significant amount of space, which can make the inclusion of anesthesia equipment (machine, cart, pumps, monitors) challenging. Ceiling lead screens and procedure table lead skirts are typically not available to the anesthesiology team and thus protection from radiation often requires the use of portable lead screens wheeled between the anesthesia area and the fluoroscopy equipment.

The anesthesiologist should become familiar with the contents of each procedure room. Gas outlets and suction, monitors for vital signs, the cardioverter-defibrillator, emergency medications, and airway equipment are critical and may not be optimally or even obviously placed. Longer tubing or extensions may be needed for ventilator hoses, intravenous lines, and suction. Electrical outlets may not be sensibly located, requiring the use of extension cords. Other equipment frequently found in these rooms may include ventricular assist devices, IABP, device programmers, and echocardiography machines. Space can become an issue during complex cases when a plethora of equipment is needed.

The fluoroscopy table and fluoroscopy equipment are controlled by radiology technicians and cardiologists. These move during the procedure to facilitate imaging, sometimes with no warning. As with all NORA locations, the local availability of extra equipment and an emergency airway cart becomes essential when the anesthesia workroom is not nearby. With cardiac patients, time can be especially critical. An anesthesia cart stocked with intravenous lines, airway equipment, and essential medications is important in the electrophysiology and catheterization laboratories. All personnel in the laboratory should be informed about the location and names of emergency equipment, particularly when an anesthesiologist is working alone.

Anesthesiologists in the Electrophysiology Laboratory

Clinical electrophysiology has redefined itself over the past 20 years (see also Chapter 38). Advanced technology and increased demand have driven exponential growth in the number of electrophysiology procedures. Additionally, the scope of these procedures has also dramatically changed from simple diagnostic procedures to major life-saving therapeutic interventions. More than 14 million Americans are affected by arrhythmias and approximately 6 million are affected by heart failure,[77] many of whom require hospitalization and complex medical care. ICDs reduce mortality and morbidity in those with malignant tachyarrhythmias as well as in patients with a reduced ejection fraction,[78] and as a result, implantations and revisions of these devices have skyrocketed.[79]

The performance of many of these procedures frequently mandates the administration of general anesthesia because of procedure duration and patient comorbidities that increase the difficulty of tolerating a procedure with sedation alone. Optimal anesthetic planning requires the anesthesiologist to integrate patient comorbidities, the nature of the arrhythmia, and the tempo and framework of electrophysiology procedures. This section reviews the most commonly performed electrophysiology procedures.

DIAGNOSTIC ELECTROPHYSIOLOGY STUDIES

Abnormal heart rhythms occur from many etiologies and range from being asymptomatic to creating hemodynamic instability and cardiac compromise. In general, these rhythms result in uncoordinated or ill-timed contractions and can be too slow or too fast. Bradyarrhythmias arise from either abnormal impulse generation or abnormal impulse propagation, and the disease may occur at the level of the sinus node, the atrioventricular node, or the His-Purkinje system. Tachyarrhythmias that are regular with a normal QRS include supraventricular tachycardias (SVT) such as atrial flutter, atrioventricular nodal reentry tachycardia (AVNRT), atrioventricular reciprocating tachycardia (AVRT), and atrial tachycardia. Supraventricular tachyarrhythmias with a normal QRS that are irregular include atrial fibrillation and multifocal atrial tachycardia. Tachyarrhythmias with a wide QRS may still be reflective of a supraventricular tachyarrhythmia but with aberrancy due to a preexisting bundle branch block or may originate within the ventricle as a ventricular tachycardia (VT).[80,81]Arrhythmias can have many etiologies including overactive electrical foci or structural heart disease leading to scar-triggered electrical activity. Common electrophysiologic generators of arrhythmias include abnormal automaticity, anatomic reentry, and triggered activity.

These abnormalities can be identified with diagnostic electrophysiology studies, which are usually undertaken in conjunction with a therapeutic procedure to either treat a specific arrhythmia or place a device (see also Chapter 38). Diagnostic studies can determine the electrophysiologic etiology of specific symptoms or events. Intracardiac recordings are made from catheters placed via femoral venous access into the high right atrium, bundle of His, coronary sinus, and right ventricular apex or right ventricular outflow tract. Arrhythmias are induced by programmed stimulation.[82] For these studies, sedation with benzodiazepines and short-acting opioids is usually sufficient. Drugs that may affect inducibility of certain arrhythmias should be avoided.

CATHETER ABLATION

Treatment of certain arrhythmias may be accomplished using percutaneous catheter-based ablation techniques. Radiofrequency energy (thermal injury) and cryotherapy (cold-induced injury) are most commonly used for ablation; both energy sources can be painful when delivered to target tissues. Ablation techniques are used for arrhythmias that are refractory to pharmacologic therapy. These arrhythmias may include SVTs such as AVNRT, Wolf-Parkinson-White syndrome (antidromic AVRT), atrial flutter, and atrial fibrillation. With regard to atrial fibrillation: recent American College of Cardiology (ACC) and American Heart Association (AHA) Atrial Fibrillation Guidelines state that in patients with little or no left atrial enlargement, catheter ablation is a “reasonable alternative to pharmacologic therapy” to help prevent recurrence of atrial fibrillation.[83] Atrial fibrillation may be treated with pulmonary vein isolation or, if complicated by an uncontrollable rapid ventricular response, ablation of the atrioventricular node and placement of a permanent pacemaker. In select patients, VT can be treated with ablation as well, such as that arising from coronary artery disease or arrhythmogenic right ventricular dysplasia.[84]

During ablation procedures, catheters are placed throughout the cardiac chambers and programmed stimulation is performed from different sites to induce tachyarrhythmias. Complex mapping techniques localize the source of the arrhythmia to identify the exact intracardiac location to which the energy must be applied. Because of the precision required for mapping and the application of energy, a still field is required. Many catheter ablation procedures, such as atrial flutter ablations, can be performed with sedation; sedation may, in fact, be preferred as arrhythmias can be suppressed with general anesthesia. However, procedures such as atrial fibrillation ablations can require 4 to 6 hours of procedure time followed by a 30-minute observation time after ablation with repeat stimulation (sometimes with the application of pharmacologic agents such as isoproterenol or adenosine) to ensure success of the procedure.[84] These longer procedures may be challenging to conduct with monitored anesthesia care as undersedation may result in back pain and patient movement, and oversedation may result in snoring or partial airway obstruction with resultant swinging of the intraatrial septum making transseptal catheter placement difficult; hence, general anesthesia may be required for optimal procedural conditions and patient comfort.

The quest for a near static field has led to the rising use of HFJV, particularly in atrial fibrillation ablations because sustained contact between the catheter and the area around the pulmonary veins is often required. HFJV aims to eliminate cardiac translation in the thoracic cavity due to tidal ventilation and reduce the potential for catheter instability[85]; this technique may decrease procedure time,[86] though patient and proceduralist characteristics such as ejection fraction and case volume performed by the electrophysiologist may be influential.[87] HFJV typically requires monitoring of arterial CO_2 either via arterial blood gas analysis or with intermittent traditional mechanical ventilation to obtain an end-tidal CO_2 measurement. Hypercarbia refractory to adjustments in jet ventilation settings may require a transition back to traditional ventilation. Due to the unpredictable delivery of volatile anesthetic with HFJV, total intravenous anesthetic techniques are typically necessary.

The anesthetic management of electrophysiologic ablation procedures involves several other concerns.[88,89] Paralysis should be avoided during ablation so that phrenic nerve stimulation and activity can be used as an alert to avoid its injury; remifentanil or sufentanil infusions can be administered in this setting. The esophageal temperature should be monitored for conductive heat transfer to the esophagus, which can result in esophageal injury; the correct position of the temperature probe can be verified easily with fluoroscopy. Radiofrequency (as opposed to cryotherapy) ablation may require irrigation, which can result in the administration of a substantial amount of fluid to the patient over the duration of the case; a careful tally and regular assessment of fluid balance may alert the anesthesiologist to the potential need for diuretic administration. Finally, cardiac tamponade may rarely occur as a result of ablation or wire perforation; this uncommon complication should be considered in the differential of hypotension of unknown origin or with narrowing of the pulse pressure. A diagnosis of tamponade can be confirmed with ultrasound (transesophageal, intracardiac, transthoracic) and requires reversal of heparin with protamine, placement of a pigtail catheter for drainage, and the potential involvement of a cardiothoracic surgeon.

Arterial line monitoring may be necessary for VT ablations due to the nature of the arrhythmia being induced. Arterial lines may not be required for other ablations (atrial fibrillation and other SVTs) unless desired for HFJV or for monitoring of patients with ventricular dysfunction, who may also require inotropic and vasoactive agents to maintain hemodynamic stability during arrhythmia induction. Close communication with the cardiologist is necessary in these situations. Frequently, electrical cardioversion is necessary during these cases.

ELECTROPHYSIOLOGIC DEVICES

Devices for the treatment or control of arrhythmias have diminished in size and increased in sophistication over the past 10 years (see also Chapter 38). More patients qualify for device implants, and hence the number of procedures for implantations, revisions, battery changes, and upgrades of devices has grown. The two most common types of devices are ICDs and pacemakers.

Implantable Cardioverter-Defibrillators

ICDs have been demonstrated to be efficacious and safe in a number of large, prospective multicenter randomized trials in patients with and without coronary artery disease. ICDs have been found to be particularly beneficial in patients with depressed left ventricular ejection fractions (35% or less).[90] The ACC, AHA, and the Heart Rhythm Society (HRS) guidelines detail the indications for ICD implantation and the conditions for which these devices prolong life and decrease the risk of sudden cardiac death.[91] With the advent of smaller biphasic, transvenous ICDs and experience gained over the years, it is now feasible for electrophysiologists to implant ICDs safely in the pectoral position in the electrophysiology laboratory. Local anesthesia combined with conscious sedation is frequently used for these procedures. Defibrillation threshold testing may be performed, and in these instances the role of the anesthesiologist may be crucial, particularly if patients have significant comorbidities. Testing the device requires deep sedation or general anesthesia and can be accomplished without an arterial line. External cardioverter-defibrillator pads are placed on the patient at the beginning of the procedure and serve as backup if the implanted device fails during the test. Defibrillation threshold testing is sometimes omitted due to elevated risk of the procedure in patients who may not have adequate physiologic reserve (such as those with untreated coronary artery disease). In addition, the newer ICDs may obviate the need for such maneuvers.

Subcutaneous ICDs (S-ICDs), which eliminate the need for transvenous leads, are also available for implantation. Although these devices detect and treat malignant VT and VF, they are incapable of providing anti-tachycardia pacing, advanced diagnostics, or radiofrequency interrogation with remote monitoring, and therefore are not appropriate for all patients. Implantation of these devices requires tunneling of a relatively large lead, which can be painful enough to require deep sedation or general anesthesia.[92]

Pacemakers

Pacemakers may have one lead (typically right ventricular), two leads (right atrial and right ventricular), or three leads (right atrial, right ventricular, and left ventricular via the coronary sinus) for the purpose of providing coordinated biventricular pacing for cardiac resynchronization therapy (CRT). CRT with and without defibrillation systems is prescribed for both primary and secondary prevention of sudden cardiac death in patients with heart failure associated with both an ischemic and nonischemic etiology. The ACC/AHA/HRS guidelines gave CRT with or without an ICD a class I indication for those with a left ventricular ejection fraction 35% or less with a QRS duration 120 ms or greater and drug-refractory New York Heart Association functional class III or IV heart failure who are receiving optimal medical therapy.[91]

While single and dual lead pacemaker placements may be accomplished with conscious sedation and standard monitors, the anesthetic strategy for the implantation of biventricular ICDs requires greater thought. CRT implantation may be successfully accomplished with sedation but could require general anesthesia for a number of reasons. For example, the indications for CRT also function as significant patient comorbidities (e.g., ejection fraction less than 35% secondary to coronary artery disease or valvular heart disease that could be associated with pulmonary hypertension and right ventricular dysfunction), which may impact on the safety of performing sedation. These procedures may be complex and lengthy because of difficulty in positioning the left ventricular lead into the coronary sinus and great cardiac vein in the setting of distorted ventricular anatomy due to cardiac dilatation and advanced heart failure. In addition, valvular regurgitation can complicate lead positioning. Finally, lead dislodgement may occur immediately after lead placement, especially in patients with a large coronary sinus, further prolonging these procedures.

During any device placement, pneumothorax or coronary sinus perforation related to lead placement is possible. Coronary sinus perforation can immediately be recognized by contrast extravasation. Perforation of the coronary sinus or cardiac perforation related to right atrial or ventricular lead placement may cause cardiac tamponade, necessitating immediate pericardiocentesis. Paralytics should be avoided as well, so that lead placement resulting in diaphragmatic pacing can be immediately identified and avoided.

Anesthesiologists in the Catheterization Laboratory

Anesthesiology in the catheterization laboratory reflects the evolving range of therapies performed in this venue. Catheterization laboratories—initially the workplace of interventional radiologists (who were the "original" angiographers)—are now home to interventional cardiologists, vascular surgeons, and others who practice a broad range of therapies. All of these practitioners use fluoroscopy and a host of ever more sophisticated interventional technologies. Procedures can be peripheral or cardiac and range from the stenting of narrowed vessels to the implantation of prosthetic heart valves. Anesthesiology involvement ranges from providing monitored anesthesia care to providing a full cardiac anesthetic and performing transesophageal echocardiography (TEE) during the case.

PERCUTANEOUS CORONARY INTERVENTIONS

Percutaneous coronary interventional procedures for patients with both stable coronary artery disease and acute coronary syndromes have grown in the past 10 years. Percutaneous coronary interventions (PCIs) include coronary angioplasty (mostly performed immediately before coronary stenting) with both bare metal stents and drug-eluting stents, atherectomy procedures, and intracoronary thrombectomy procedures. PCI procedures are commonly performed in patients with 70% or greater intracoronary luminal atherosclerotic obstruction and myocardial ischemia in the context of stable coronary disease. The major benefit of PCI is to reduce or relieve symptoms of ischemic heart disease and increase aerobic capacity.[93] No significant difference in total mortality, nonfatal myocardial infarction, or other major cardiovascular events were demonstrated between patients randomized to aggressive medical therapy versus aggressive medical therapy plus PCI angioplasty with bare metal stenting.[94] But for patients who presented with acute coronary syndromes, PCI decreased mortality and recurrent myocardial infarction in contrast to medical treatment alone.[95]

PCIs can be performed with mild to moderate nurse-administered sedation under the direction of the cardiologist. Anesthesiologists are usually involved only when patients present with known severe comorbidities (e.g., oxygen-dependent COPD, opioid tolerance) or with the development of respiratory or hemodynamic compromise. If acute respiratory or hemodynamic decompensation occurs, anesthesiologists are often called emergently. In these circumstances, clear and direct communication with the cardiologist is required and management decisions usually need to be made expeditiously. Information such as medications given, intravenous access, and stage of the procedure must be communicated. As mentioned previously, access to the patient's head can be difficult due to x-ray equipment. If an airway needs to be established, it may be necessary to temporarily move the table and fluoroscopy equipment. Placement of an endotracheal tube is preferred to a LMA even in an elective situation because constant movement of the equipment can dislodge the LMA; however, an LMA can serve as a temporizing measure if placement of an endotracheal tube is difficult. During PCI, patients can be in a highly anticoagulated state, and a bleeding difficult airway is a nightmare in this context.

INTRAAORTIC BALLOON PUMPS AND PERCUTANEOUS VENTRICULAR ASSIST DEVICES

The IABP is a mechanical device inserted percutaneously into the aorta that increases myocardial oxygen delivery and cardiac output. The balloon, sitting approximately an inch distal to the subclavian artery, inflates and deflates in diastole and systole, respectively, thereby delivering counterpulsation. This increases coronary blood flow and myocardial oxygen delivery and decreases afterload resulting in a rise in cardiac output. The balloon pump is controlled by a programmed console, which inflates the balloon at time intervals linked to either an electrocardiogram trace or a pressure transducer at the distal tip of the catheter. The placement of an IABP is usually successful under conscious sedation unless the patient is compromised from a hemodynamic or respiratory standpoint, in which case the team may seek assistance from an anesthesiologist.

Percutaneous ventricular assist devices (PVADs) can provide cardiac output support during high-risk PCI or cardiogenic shock associated with myocardial infarction. Several types of PVADs are available. The TandemHeart device (CardiacAssist, Philadelphia, Pennsylvania) is a percutaneous left-atrial to femoral arterial bypass system consisting of a transseptal cannula, an arterial cannula, and an externally located centrifugal blood pump, which can deliver flow rates of up to 4 L/min.[96] An alternative percutaneous-based left ventricular assist device is the Impella (Abiomed, Danvers, Massachusetts), which comes in three sizes: 2.5, CP, or 5.0; cardiac outputs of either 2.5 L/min, 4.3 L/min, or 5.0 L/min can be achieved with these devices, respectively.[97] The Impella uses a cannula inserted retrograde via the femoral artery into the left ventricle across the aortic valve. These pumps do not require transseptal puncture, are smaller and easier to implant, and incorporate a microaxial pump into the catheter system thereby eliminating the need for extracorporeal blood. Anesthesiologists are often consulted for placement of these devices because the patients are unstable and/or present with a high likelihood of hemodynamic compromise. Depending on the procedure and state of the patient, either sedation or general anesthesia can be used. These devices achieve cardiac outputs that can completely replace left ventricular function; blood flow may not be pulsatile, so pulse oximetry and noninvasive blood pressure cuffs may not work properly. However, invasive monitoring is available via the arterial cannulation used during the procedure and arterial blood gas analysis can provide information on gas exchange. The choice of anesthetic, likely postprocedural care, and prognosis should be discussed with the cardiologist before the start of the case, if possible.

PERCUTANEOUS CLOSURE OF SEPTAL DEFECTS

The percutaneous closure of septal defects includes closure of PFOs and secundum atrial septal defects (ASDs). Initial studies assessing the efficacy of percutaneous closure of PFOs in patients who have suffered from a cryptogenic stroke showed no benefit.[98-100] However, these studies have recently been supplanted by several multicenter randomized controlled trials showing decreased rates of recurrent stroke, particularly in young patients with large shunts.[101-104] The Food and Drug Administration (FDA) approved use of the Amplatzer PFO Occluder (St. Jude Medical Inc., St. Paul, Minnesota)[105] based on the results of one of those studies, the RESPECT trial, which showed a 50% reduction in the rate of new strokes in patients using the occluder plus blood-thinning medications compared with blood-thinners alone.[103]

The Amplatzer Septal Occluder is used in clinical practice for closure of secundum ASDs. This occluder is a two-sided "clam shell" made up of two flat discs with a middle or "waist." The discs are made of nitinol (nickel and titanium) wire mesh and polyester fabric inserts, the latter of which create a nidus for tissue growth after placement.[106] The closure of PFOs tends to be simpler than the closure of ASDs. In patients with ASDs, it is important to clarify right ventricular function, pulmonary arterial pressures, and shunt fraction to formulate an optimal anesthetic plan. Success rates for PFO and ASD closure range from 79% to 100%.[107]

These occluder devices can also be used to close other types of defects such as paravalvular leaks and muscular or perimembranous ventricular septal defects (VSDs), either congenital or acquired. Reportedly, VSDs can be closed 96% of the time, with a 2% major complication rate with these devices.[108] In patients with traumatic (postmyocardial infarction) VSDs, hemodynamic instability is not unusual and complications are common during closure attempts. Tissue integrity is frequently compromised making placement of closure devices difficult. Visualization of the defect and guidance of device placement can also be challenging. Patients with postmyocardial infarction VSDs are more likely to have complications during closure of the defect.[109]

Complications of any device placement in the cardiac catheterization laboratory include air embolism, device embolization, malposition, thrombosis, arrhythmias, hypotension, valve dysfunction, cardiac perforation, and injury to non-target cardiac structures. It is critical that these complications be recognized and dealt with expeditiously. Rapid and effective communication is critical. Untoward events may be evident initially to anesthesiologists if they are guiding the procedure with TEE.

Echocardiography is often used during the placement of intracardiac septal occluder devices to help guide placement and confirm a successful result. TEE can be performed by cardiologists, anesthesiologists, or ultrasound technicians depending on institutional preference and availability of personnel, and if used, requires general anesthesia (see also Chapter 37). Although two-dimensional (2D) echocardiography is the most widely used imaging technique for preprocedural patient evaluation, multidetector row CT and cardiac MRI can also help to delineate structural intracardiac details. Intraprocedural three-dimensional (3D) TEE is also available.[110] Intracardiac echocardiography (ICE) can be used to guide the procedure, but this must be performed by the cardiologist because the controls are at the groin in the field. In cases in which TEE is not available or cannot be performed because of patient comorbidities, ICE is a reasonable alternative, in which case general anesthesia may not be needed.

PERIPHERAL ARTERIAL DISEASE

Peripheral arterial disease affects approximately 8 million Americans (see also Chapter 56). The prevalence of this disease increases with age and occurs more commonly in African Americans. Intermittent claudication and rest pain are the principal symptoms. Claudication occurs as a result of insufficient arterial blood flow and leg ischemia and is often described as pain, aching, or a sense of fatigue that is relieved at rest. Symptoms are most often experienced in the muscle bed supplied by the most proximal stenosis. Buttock, hip, or thigh claudication is related to obstruction of the aorta or iliac flow, calf claudication is commonly a result of either femoral or popliteal arterial stenosis, and ankle or pedal claudication is typically caused by either tibial or peroneal disease.[111]

According to ACC and AHA guidelines, percutaneous revascularization in patients with intermittent claudication should be considered when any one of the following circumstances is encountered:

1. Claudication symptoms significantly disable the patient.
2. The patient would benefit from an improvement in exercise.
3. Rehabilitation and pharmacologic therapy have not provided an adequate response.
4. A favorable risk-to-benefit ratio to performing the procedure exists.
5. The characteristics of the lesion permit appropriate intervention at low risk with a high likelihood of initial and long-term success, and/or the patient has limb-threatening ischemia, as manifested by rest pain, ischemic ulcers, or gangrene.[112]

The majority of cases are performed with sedation. The anesthesiologist may be critical to the interventional cardiologist during a peripheral vascular intervention because many of these patients are unable to lie still during the procedure because of rest pain symptoms and other related comorbidities. In addition, the procedure itself may create painful transient ischemia resulting in patient movement that may reduce the likelihood of success. Anesthesia care may also be required when the procedure is technically difficult and the patient is unable to cooperate or when vascular injury has occurred (i.e., formation of a hematoma).

PERCUTANEOUS VALVE REPAIR AND REPLACEMENT

Percutaneous technologies for the treatment of mitral regurgitation and aortic valve disease are presently available with ongoing development of devices and approaches. These procedures are a major addition to the repertoire of interventional cardiologists and represent an exciting new overlap of surgical and medical therapies for structural heart disease.

PERCUTANEOUS MITRAL VALVE REPAIR

Surgical repair is typically indicated for the treatment of symptomatic mitral regurgitation (with LVEF >30%) or asymptomatic mitral regurgitation with impaired left ventricular ejection fraction (EF 30% to ≤60%).[113] However, alternate techniques of percutaneous mitral valve repair are under investigation including leaflet repair, direct annuloplasty, and coronary sinus annuloplasty.[114]

Mitral regurgitation can be percutaneously repaired by placement of a MitraClip (Abbott Vascular, Abbott Park, Illinois), a clip-like device that creates an Alfieri edge-to-edge repair. After a transatrial septal puncture, the clip is positioned in the center of the mitral valve orifice. The clip is opened, passed into the left ventricular cavity, pulled back to contact the mitral valve leaflets, and then closed to create a double-orifice mitral valve.[114] Direct mitral valve annuloplasty such as with the Cardioband system (Valtech Cardio, Inc., Or-Yehuda, Israel) mimics a surgical annuloplasty but delivers the device transseptally and implants on the atrial side of the annulus using multiple anchor elements.[115,116] Devices that use the coronary sinus as a method of cinching the mitral annulus are investigational, and the safety and efficacy of this approach remains undetermined. General anesthesia, fluoroscopy, and TEE are used to help guide placement of these devices.[107]

Percutaneous Aortic Valve Replacement (Transcatheter Aortic Valve Replacement)

Percutaneous aortic valve replacement or transcatheter aortic valve replacement (TAVR) is a relatively new treatment in the U.S. for aortic stenosis. During the procedure, a replacement valve is crimped into a catheter and passed through the femoral artery to the aortic annulus. Rapid ventricular pacing is employed to minimize cardiac output while the prosthesis is deployed into the appropriate position after a balloon valvuloplasty. Transaortic and transapical insertions of transcatheter valves can also be performed by a multidisciplinary team in a hybrid OR setting. In the future, other variants of this procedure will likely evolve for placement of valves in other positions.

The concept of a transcatheter valve for percutaneous placement was initially presented in the early 1990s, and the first percutaneous heart valve for human use was developed by Cribrier and implanted in Europe in 2002.[117,118] Two devices currently exist for percutaneous implantation: the Edwards Lifesciences SAPIEN (Edwards Lifesciences, Irvine, CA) and the Medtronic CoreValve (Medtronic, Minneapolis, Minnesota). The Edwards SAPIEN valve received FDA approval in November 2011 and the CoreValve in January 2014.[119,120] The SAPIEN valve is a bovine pericardial prosthesis sutured into a balloon-expandable tubular metal stent, while the CoreValve is a porcine pericardial self-expanding valve prosthesis sutured into a nitinol stent.

The population of patients eligible for TAVR has expanded from patients who are not surgical candidates[126] to those who are high-risk surgical candidates,[121] and now encompass patients who are considered only intermediate-risk.[122] In high-risk patients with severe aortic stenosis, TAVR was found to be noninferior to surgical aortic valve replacement at 1 year in terms of survival. However, the transcatheter procedure was associated with a higher risk for stroke than the surgical replacement at 1 year and a higher risk for major vascular complications at 30 days. More patients undergoing TAVR demonstrated improved symptoms at 30 days, but no significant between-group difference was seen at 1 year.[121] In intermediate-risk patients, the rates of both death and disabling stroke at 2 years were comparable to those who underwent surgical aortic valve replacement; however, similar to the trial studying high-risk patients, the TAVR group had more major vascular complications and also showed improved symptoms compared with the surgery group at 30 days but not at other time points.[122] The use of TAVR for treatment of failing aortic bioprostheses (with valve-in-valve therapy) due to either stenosis or regurgitation has also been increasing. The rapid expansion of indications for TAVR has prompted a task force examining appropriate use criteria of this technology.[123]

CTs are typically obtained before the procedure to define valve size and anatomy. Patients are frequently elderly with severe valvular disease and attendant comorbidities; thus, planning for expected difficulties related to patient comorbidities and technical challenges is well worth the extra time. A team meeting before the procedure is worthwhile because elements of the patient's history often warrant interdisciplinary scrutiny and discussion.

Transfemoral TAVR can be performed in a cardiac catheterization laboratory or hybrid OR. At our institution, all percutaneous valve repairs are performed under general anesthesia with fluoroscopic and TEE guidance. As technology improves, the flow of cases will change. Presently, however, at our institution, the following list constitutes the framework for transfemoral cases:

Critical Procedural Steps During Transfemoral Transcatheter Valve Replacement

1. Place intravenous line and arterial line, induction.
2. Place PA line, larger access, cerebral SvO_2.
3. Conduct TEE, discussion of expected and unexpected findings with entire team.
4. Access femoral vasculature: arterial sheath, contralateral transfemoral aortic occlusion balloon, and place transvenous pacer.
5. Perform standard balloon aortic valvuloplasty: refine sizing and enlarge orifice.
6. Assess adequacy of rapid ventricular pacing.
7. Upsize sheath to (27 Fr) or appropriate introducer.
8. Advance transcatheter valve; assess position by fluoroscopy and echocardiography.
9. Deploy valve during rapid ventricular pacing.
10. Assess valve position and function.
11. Remove sheath and complete vascular closure.

Large peripheral intravenous lines should be placed for volume administration. Invasive arterial pressure monitoring is important because noninvasive blood pressure cuffs may not work when the patient is rapidly paced. Central access is useful for infusions and a Swan-Ganz catheter is recommended in compromised patients.

TEE plays a critical role in the management of patients undergoing TAVR (also see Chapter 37). Before any intervention, aortic stenosis with a trileaflet valve should be confirmed—TAVR cannot be performed with bicuspid valves. The degree of aortic insufficiency should be assessed before valvuloplasty, as the presence of preoperative mild to moderate aortic insufficiency may be protective in severe new-onset cases after balloon aortic valvuloplasty. Ejection fraction, degree of mitral and tricuspid regurgitation, presence of mitral annular calcification and mitral stenosis, estimated pulmonary artery pressures, and coronary artery takeoff location are also useful measurements. Accurate measurement of the aortic annulus aids in the choice of prosthetic valve size.

During the placement of the valve, real-time echocardiographic guidance, either 2D or 3D, can assess positioning of the prosthesis. Multiple attempts may be needed to ensure proper catheter and device placement with an acceptable result. Following valve deployment, rapid assessment of valve position, function, and perivalvular and central leaks is crucial; verification of the patency of the coronary ostia and absence of new ventricular wall motion abnormalities is critical as well. Communication and visual accessibility to all imaging during the procedure is vital to successful placement of the device. Patients may develop hemodynamic instability, myocardial ischemia, or significant arrhythmias during the case, so constant communication between anesthesiologist and cardiologist is critical. Planned extubation is reasonable assuming the patient's comorbidities and the course of the procedure warrant it.

Multiple aspects of this procedure may evolve in the future. For instance, the percutaneous femoral approach requires adequate endoluminal diameters, but as technology develops, smaller sheaths and more flexible valves will become available. Thus, in the future, tortuous iliac vessels or high athermanous burden may not preclude a femoral approach. In addition, the merits of intraprocedural TEE versus transthoracic echocardiography or fluoroscopy alone are under active debate.[124] Similarly, while general endotracheal anesthesia is preferred, institutions in the U.S. and Europe have reported successful outcomes with conscious sedation.[125]

Common Complications and Remedies

Vascular Avulsion, Perforation, or Dissection. A number of vascular problems can occur during insertion and removal of the introducer sheath. Vascular dissection or perforation, while rare, are known complications. Femoral vascular avulsion is possible on removal of the introducer sheath. Temporization of hemorrhage can be achieved with the distal aorta occlusion balloon residing in the contralateral femoral artery. This can prevent fatal hemorrhage in the event of a vascular catastrophe. If percutaneous access cannot be obtained, cut-downs or surgical access to the aortic bifurcation is possible. Vascular surgical repair is necessary in this situation.

Pacing Malfunction. Transvenous pacing is used to establish rapid ventricular pacing and a near-zero cardiac output state during ballooning of the aortic valve. If atrioventricular node dysfunction occurs after valvuloplasty or valve deployment, postdeployment pacing may be necessary. Poor communication during rapid ventricular pacing may be catastrophic. Loss of pacer capture during balloon valvuloplasty can place excessive traction on the native valve during balloon inflation, and unexpected ventricular ejection can embolize the valve from the annulus during deployment.

Valve Deployment. Patients respond idiosyncratically to balloon valvuloplasty; new-onset aortic insufficiency may require significant support and necessitate rapid valve introduction and deployment. Inotropic support may be necessary to maintain systemic blood pressure as balloons and crimped valves traverse the valve orifice. Invasive monitors typically reflect low cardiac outputs, falling cerebral SvO_2s, and high pulmonary artery pressures. The authors routinely have boluses of epinephrine, norepinephrine, and vasopressin available in a variety of concentrations.

Valves left prepared on the balloon but not deployed for significant amounts of time may open improperly, causing significant aortic insufficiency. Deployment of an additional device (valve-in-valve) may be necessary in this case.

Device Embolization. Embolization into the aorta can occur as a result of ejection because of inadequate pacer capture or inappropriately high deployment. Once a valve is in the aorta, it is irretrievable endovascularly. Valves lodged in the descending aorta have been reported and are tolerated; however, a second valve must still be deployed in the aortic position. Valve loss into the ventricle may occur if deployment is too low. This result requires surgery for retrieval and may be fatal if comorbidities are significant.

Coronary Occlusion. Coronary occlusion is a potential problem if calcium or native aortic valve tissue occludes a coronary ostium. Prior coronary artery bypass graft with patent grafts is partially protective. Coronary guidewires may be placed in patients who are at higher risk. Skilled intervention is required to reopen occluded coronary arteries. Clear interdisciplinary communication is essential in the management of regional wall motion abnormalities, ST-segment changes, or hemodynamic compromise.

Need for Cardiopulmonary Bypass. Cardiovascular collapse during transfemoral procedures may require cardiopulmonary support. Institutional variability exists regarding the type of support planned. Some institutions have a primed cardiopulmonary bypass pump in the room, even if the case is in a catheterization laboratory outside of the OR; others have percutaneous VAD support on standby.

Neurologic Events. Acute stroke is potentially detectable with unilateral changes in cerebral oximetry readings. The higher stroke rate of cohort A patients in the PARTNER trial was felt to be a result of both the introduction of a large balloon and valve apparatus across the aortic arch and ballooning of the calcified native valve. Anesthetics allowing for early neurologic assessment are preferred.

As patient acuity increases, safe and efficient care for the target population in the cardiac catheterization and electrophysiology laboratories is a concern for all anesthesiologists and cardiologists. Anesthesiologists are uniquely trained to care for this complicated patient population while permitting cardiologists to focus on the interventional procedure. Anesthesiologists, in collaboration with cardiologists, must establish guidelines for the interdisciplinary care of patients with complex issues. The goal is to enhance patient safety, procedural efficiency, and outcomes while advancing the frontiers of medical care in venues outside of the OR.

Interventional Echocardiography Anesthesiologists as Co-Proceduralists—The Road Ahead

As percutaneous interventions for structural heart disease increase in number and broaden in scope, the need for multidisciplinary input grows. Cardiac anesthesiologists traditionally perform TEE in the OR before and after cardiopulmonary bypass to diagnose structural problems and assess surgical repair. In the catheterization laboratory, growing usage of general anesthesia to support patients during complex procedures ideally positions cardiac anesthesiologists to perform this service in a new context.

Diagnostic echocardiography is important in the catheterization laboratory, as it is in the OR. However, the novel feature of TEE performed in the catheterization laboratory (interventional TEE) is the need for step-by-step guidance of intricate and highly technical intracardiac manipulations (see also Chapter 37).[126] Fluoroscopy—the traditional imaging modality for interventional cardiology procedures—entails significant radiation exposure, requires the use of intravenous contrast, and can be temporally and spatially imprecise. Interventional TEE provides precise adjunctive imaging for placement or removal of intracardiac devices, placement of transcatheter valves, and repairs of paravalvular leaks or other structural defects. In addition, cardiac anesthesiologists understand imaging in the context of anesthetic care and are capable of manipulating hemodynamics as observation of cardiac function requires. Functional interpretation of structural defects can be critical as repairs are made. In the catheterization laboratory or hybrid OR setting, cardiac anesthesiologists become co-proceduralists providing imaging, hemodynamic control, interpretation, and step-by-step guidance for interventionalists in the context of fixing abnormal cardiac anatomy. Real-time 3D guidance during catheter placement, ballooning, or device implantation is an important and new component of interventional cardiology. This is a time-sensitive, high-acuity undertaking. It is relatively new in intracardiac imaging and for cardiac anesthesiologists; it defines an exciting and important role that goes a step beyond the job of maintaining homeostasis during the stress of surgery.

Interventional TEE is performed during septal occlusion, paravalvular leak repair, and transcatheter valve replacement. As in the OR, comprehensive interventional TEE examination begins with assessment of cardiac structure and function in the context of the proposed procedure, including the primary defect and any associated pathology. Effective communication among team members is critical because the value of interventional 2D and 3D TEE is lost if mutual understanding is absent. To this end, information from fluoroscopic and echocardiographic images can augment each other when unusual anatomy or clinical circumstances are observed. Data from each imaging modality should be discussed if contradictory interpretations arise.

Interventional TEE includes both 2D and Doppler imaging complemented by 3D and real-time 3D assessments. It may be important to alternate between 2D and 3D imaging to clarify temporal and spatial details[127,128] so that accurate placement of wires and catheters can occur. Closure of paravalvular leaks or stenting of stenotic pulmonary veins, for example, may require both types of imaging. Real-time 3D imaging can clearly depict the proximity of equipment and devices to targeted defects by permitting rotation of acquisitions in all directions, thereby delineating structures in their native orientation. Although in the OR it is possible to correlate actual anatomy with TEE images while the chest is open and the patient is on bypass, this is not the case during percutaneous procedures. The accuracy of imaging and interpretation is therefore critical.

During TAVR, interventional echocardiography is important for optimization of valve placement and diagnosis of problems when they occur. After TAVR deployment, a comprehensive TEE is performed. Valve position and function is assessed, gradients are calculated, the absence of coronary ostial occlusion is confirmed, and the need for any remedial activity is discussed. This requires the input of proceduralists and cardiologists alike.

As technology evolves, percutaneous procedures for structural heart disease will become more sophisticated. As devices improve, the target populations will grow. Patients with congenital, acquired, and surgically created defects will become eligible for treatment by interventional cardiology procedures. Interventional TEE has emerged as the newest evolutionary phase of cardiac anesthesiology.[129] The development of collaborative relationships between interventional cardiologists and anesthesiologists provides the foundation for a robust, multidisciplinary interface, thus establishing a basis for advancement of clinical practice and a place for anesthesiologists at the forefront of medicine.

The Road Ahead: Toward a Comprehensive Strategy

As technology evolves, medical procedures performed in locations outside of the traditional OR environment will continue to increase and both the procedures and the patients who undergo the procedures will be more complex. As the population ages and medical therapies achieve increased effectiveness, more patients who in the past would not have been candidates for any intervention will be offered procedures that either prolong life or improve its quality. The current expansion of minimally invasive, nonsurgical approaches to disease will continue and, as a result of these changes, demand for anesthesiology services will escalate.

The experience with NORA procedures has taught us many lessons. Perhaps the most significant lessons include our understanding of the needs of the patients and proceduralists—and the expectation that the same standards of care will be required wherever anesthesia care is provided. As a result, anesthesiologists must be flexible, while also ensuring that the usual safeguards provided in the OR environment are extended to every other location in which we provide care. Inclusion of procedural areas within our practice requires a new model of service delivery. Over the past 30 years, anesthesiologists revolutionized safety, reliability, and the scope of perioperative practice. We must extend the same safety and quality to the care we provide in the non-OR locations. Seeing beyond the traditional role of anesthesiologists in the OR, we can create a niche as innovators of NORA in the same way that we have broadened our services by providing critical care coverage inside and outside the ICU and by widening the integration of care provided by acute and chronic pain management teams.

SOME ADDITIONAL CONSIDERATIONS

Operational Effectiveness

Operational effectiveness is a crucial component of providing clinical care in any setting. It is also required to ensure that each health system can successfully compete and remain financially solvent. For anesthesiologists providing care outside of the OR, we are critical participants in defining how care is provided and what resources are necessary to optimize care, while also being cognizant of the economics of our practices. We must provide more efficient and, in many cases, more flexible services in nontraditional settings as long as we remain attentive to patient needs and safety considerations. We also need to communicate when an anesthesia provider is required for some procedures, what equipment, supplies, and other needs must be met, and how to do so cost-effectively. To do so requires that we document our services and outcomes and evaluate alternative approaches to care in a thoughtful and evidence-based manner.

Costs, Uniqueness, and Value-Added

Anesthesiologists have the training and experience to deliver superior, integrated, and cost-effective services outside the OR. In an era of increasing medical specialization and fragmentation of care delivery, particularly in the context of accountable care organizations and bundled payments, these are the critical indices of success.

Proper variable cost accounting demonstrates that the cost of patient care involving an efficiently deployed anesthesiologist is less than the cost imposed on the whole system by those procedures that start without anesthesia personnel and end with an urgent, unanticipated call. The expense of (1) delaying a procedure, (2) stopping a procedure for inadequate or excessive sedation, (3) hospitalizing a patient, and (4) rescheduling or redoing procedures is forbidding. However, the costs are not always obvious because they are spread over multiple cost centers.

Strategic Positioning

For anesthesiologists, strategic positioning occurs when the needs of customers are satisfied with minimal cost to the anesthesiologists. The customers are not just patients—they are also medical proceduralists and third-party payers. If we can provide a safer and more comfortable, time-efficient, and cost-effective environment for proceduralists, the value of anesthesiologists will be clear. If we develop a bridge between medical and surgical treatment by facilitating hybrid procedures and interdisciplinary approaches, the overall value of our presence will be incontrovertible to proceduralists, patients, insurance companies, regulatory bodies, and government agencies.

Financial Silos and Teamwork

The increased requirements by third-party payers to provide value-based care requires that anesthesiologists work collaboratively with our colleagues to define new models of care and integrated care requires collaboration and interdisciplinary effort. As accountable care organizations and value-based care models expand, we will have to demonstrate the value the anesthesiologist provides for the NORA procedures to justify our "piece of the economic pie." Our success will depend on the strength of relationships we forge with health systems and our physician colleagues. Team building requires communication and coordination based on common experience and vocabulary. In many cases, this process will be most effective if we align anesthesiologists and other providers by service lines which collaboratively define standard approaches to care for specific patient populations. The integration of medical and surgical perspectives can facilitate innovative solutions, improve the delivery of cost-effective and efficient care, and avert mistakes outside of the OR.

Sustainable Strategy: Key Points

An effective strategy is one that maintains a dynamic and profitable market presence. Anesthesiologists have two related parallel sets of priorities: creating and maintaining a stable but flexible customer base, and achieving financial sustainability.

Operational effectiveness will ensure that appropriate resource allocation permits innovation. Enhanced core competencies resulting from expanded medical training and presence outside of the OR will provide a basis for the already needed enrichment of services. Team building will ensure that proceduralists understand the rationale for close cooperation and generate a foundation for better integrated finances. Reframing boundaries and elimination of silos will enhance integration, productivity, and the quality of care across the board. The overall strategy must be to make our specialty indispensable to customers and potential customers while enhancing the lives of patients by improving outcomes and stimulating progress.

Our expertise will generate consistent reimbursement if we have the data to demonstrate the benefit of that presence. Our participation in non-OR procedures can stimulate and advance medicine just as development of the OR environment advanced the practice of surgery. As technology continues to proliferate and diversify, the distinction between medical and surgical approaches to treatment becomes blurred. The pursuit of innovation has always been characteristic of anesthesiologists. We must continue this work in new venues and work to build bridges to continue to strengthen our specialty.

The need is urgent for anesthesiology to adopt a broader perspective. If this opportunity and its associated intellectual challenges are ignored, the status of anesthesia, a key medical subspecialty, may be threatened. If the challenge is accepted, the practice of anesthesiology will be on the front lines of changing and advancing medical science. An unprecedented crescendo of emerging technology and ongoing innovation continues to defy status quo approaches to NORA cases. Proceduralists, locations, and equipment will continue to evolve. Regardless of the venue or the technique, anesthesiologists remain a critical and constant guardian of the integrative medical perspective, patient safety, and efficient procedural processes. As we move beyond the OR, constant vigilance, dedicated teamwork, mutual respect, and effective communication will continue to be the fundamental keys to success.

Clinical Care in Extreme Environments: Physiology at High Altitude and in Space

ANDREW F. CUMPSTEY, ALEXANDER I.R. JACKSON, and
MICHAEL P.W. GROCOTT

KEY POINTS

- High altitude or space environments present a number of extreme physiologic challenges that must be overcome in order to survive.
- Given sufficient time, humans can adapt to both hypobaric hypoxia and microgravity.
- Lack of adaptation can lead to environment-specific illnesses, such as acute mountain sickness, high-altitude pulmonary edema, decompression illness, or the acute worsening of comorbid conditions.
- These conditions can rapidly become fatal if not treated appropriately (e.g., with either descent to lower altitudes or returning to the Earth's surface).
- Providing critical care or anesthesia in such environments is further complicated by their extreme levels of remoteness.
- Exploratory missions to such environments depend on the development and vetting of robust and simple health care protocols.

Introduction to Altitude and Explanation of Hypobaric Hypoxia and Its Effect on Physiologic Performance

An estimated 140 million individuals live at altitudes over 2500 m,[1] whereas sojourns to altitude are undertaken by large numbers of individuals each year for leisure, work, and religious reasons.[2-4] It can be expected that a significant proportion of these individuals will require medical care, either directly related to altitude or for any other reason. As such, there is a clear need for medical practitioners to appreciate the specific environment, physiology, and pathologic conditions at altitude.

At high altitude, a number of environmental changes may be observed. These include decreased temperature, increased ultraviolet exposure and, particularly in mountainous environments, remoteness combined with challenging access and egress, and challenging weather patterns. Overall, the area of primary focus to the critical care and anesthetic practitioner is hypobaric hypoxia and the resultant physiologic changes associated with altitude exposure.

As altitude (i.e., vertical height above sea level) increases, the barometric pressure (P_B) decreases in a nonlinear manner (Fig. 74.1), resulting in a P_B at the summit of Mount Everest (8848 m) approximately one third that of sea level. The relative concentrations of gases, including oxygen, remain static but because of the falling P_B, the partial pressure of each gas decreases. The resultant hypoxia is of great clinical significance and results in many physiologic changes. These physiologic changes vary with the time course of exposure and a number of long-term adaptations in high-altitude populations have been observed.[5] This chapter considers the high-altitude environment directly, and the consequences of it on clinical practice; however, it should be noted that many consider the hypoxia encountered at altitude to be of translational value to hypoxia at sea level, for example, in critically unwell patients.

Physiologic Responses to Hypoxia/Acclimatization

CARDIOVASCULAR RESPONSES

Initial cardiovascular changes occur rapidly. Following the initial ascent, however, more gradual changes may be observed over a period of weeks (Fig. 74.2). On exposure to hypoxia at altitude, peripheral arterial chemoreceptors are stimulated, triggering increased sympathetic activation. The resultant increased heart rate (HR) leads to a rise in cardiac output.[6] A concurrent systemic vasodilation is seen

Fig. 74.1 The symptoms and clinical effects associated with the nonlinear decrease in barometric pressure at increasing altitude. *MRI*, magnetic resonance imaging. (From Wilson MH, Newman S, Imray CH. The cerebral effects of ascent to high altitude. *Lancet Neurol*. 2009;8:175–191.)

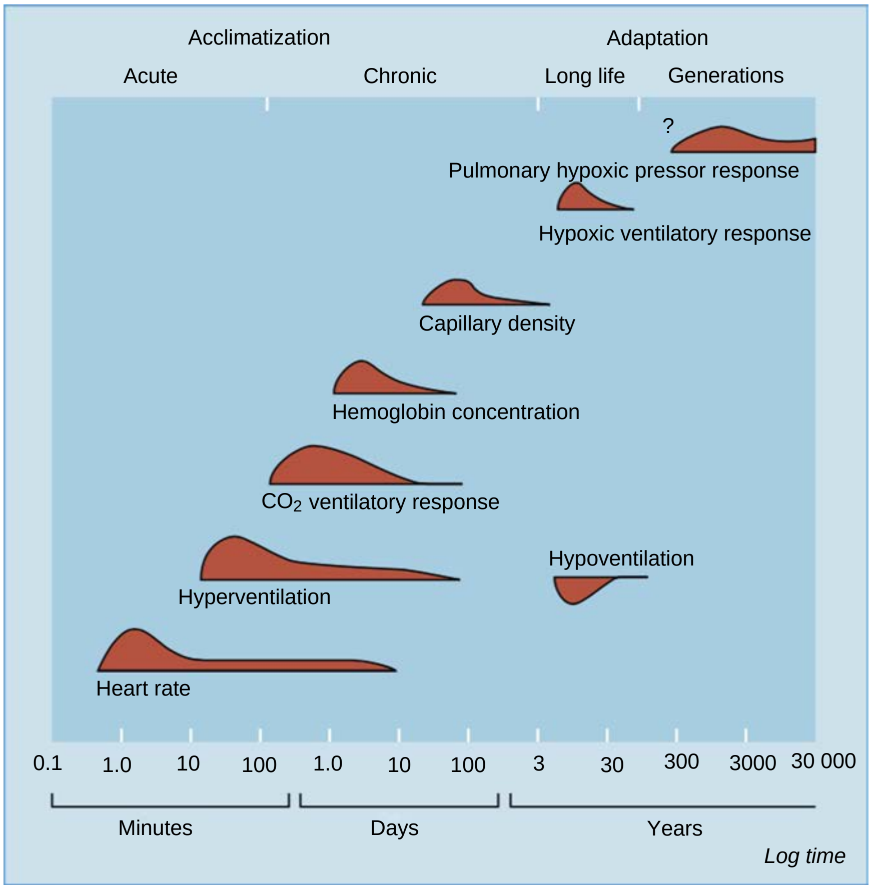

Fig. 74.2 The time course of acclimatization and adaptive responses to hypobaric hypoxia with the curve of each response representing the relative rate of change (note the log time scale). (From Peacock AJ. Oxygen at high altitude. *BMJ*. 1998;317:1063–1066.)

on ascent to altitude. This is antagonized by increased sympathetic tone and the overall effect is one of increased blood pressure (BP), although in the early hours of exposure vasodilation may predominate.[7] After several days, cardiac output returns to baseline but with a lower stroke volume (SV) and higher HR,[8] while BP continues to rise for several weeks.

This pattern of increased HR and reduced SV persists across exercise states at altitude.[9] In both athletes and nonathletes,[10] maximal oxygen consumption (VO_2 max) decreases with increasing altitude, estimated at approximately 1% per 100 m above 1500 m.[7]

Hematologically, a rise in hemoglobin (Hb) concentration is seen in response to altitude exposure. Over the initial days, this is related to a fall in plasma volume of approximately 20%,[11] followed by a rise in red cell production secondary to increased levels of erythropoietin (EPO; which begins to rise within hours of ascent).[12] This change in Hb concentration increases arterial oxygen content (CaO_2) and theoretically improves oxygen delivery (DO_2) to tissues.

However, this may be compromised because there is a marked increase in hematocrit and plasma viscosity. Viscosity has been observed to increase by 38% in healthy volunteers on ascent to 5800 m.[13] Changes in microcirculation, important for the final phase of DO_2, have been observed in vivo at altitude with a significant reduction in microcirculatory flow seen in healthy volunteers during altitude exposure, although this does not seem to be directly related to the increase in hematocrit and viscosity.[14] Subsequent studies have shown that this flow is significantly greater in the highly altitude-tolerant Sherpa population,[15] raising the possibility that such microcirculatory adaptation may play an important role in optimizing DO_2 and adaptation to high altitude.

RESPIRATORY RESPONSES

The falling P_B at altitude results in a decreased atmospheric partial pressure of oxygen (PO_2). This in turn results in reduced alveolar (PAO_2) and arterial (PaO_2) partial pressures of oxygen. However, the reduction in PAO_2 is accentuated because the saturated vapor pressure of water ($P_{SVP\ Water}$) is unchanged (6.3 kPa) at altitude. Examining the alveolar gas equation, we can see that a proportionally higher saturated water vapor at body temperature (P_{H_2O}) will result in a decreased PAO_2.

$$PAO_2 = FiO_2\ (P_B - P_{H_2O}) - (PaCO_2/R)$$

This decrease in PAO_2 leads to the hypoxic ventilatory response (HVR), which is the most important aspect of acclimatization to high altitude. Studies have found that successful climbers demonstrate an improved HVR.[16] The decrease in PaO_2 leads to hypoxic stimulation of peripheral arterial chemoreceptors,[17] which in normoxia are normally suppressed by central chemoreceptors responding to changes in carbon dioxide (CO_2). The peripheral arterial chemoreceptors trigger rapid increases in minute volume (V_E) over seconds to minutes. A resulting decrease in $PaCO_2$ also helps increase the PAO_2, as explained by the alveolar gas equation, which demonstrates that any fall in $PaCO_2$ will result in an increased PAO_2.

The resultant hypocapnia following HVR leads to a leftward shift in the oxygen dissociation curve (ODC). This shift improves oxygen uptake at the lungs, but the increase in affinity may have consequences for DO_2 at end organs.[18] A leftward shift and increased oxygen affinity of Hb are key components of the adaptive response in a number of animals who live in hypoxic conditions.[17] However, with altitude exposure in humans, this leftward shift is opposed by an increase in 2,3-diphosphoglycerate, over several days, causing a rightward shift. The final position of the curve varies depending on altitude exposure and level of acclimatization, but in sojourners it appears to equilibrate at almost sea level values, whereas certain groups of high-altitude natives are able to sustain a leftward shift through hyperventilation.[19,20]

As $PaCO_2$ decreases, a respiratory alkalosis develops in both arterial blood and cerebral spinal fluid (CSF). This alkalosis initially antagonizes HVR; however, after several hours and continuing for over 2 weeks, the body begins to correct the alkalosis through bicarbonate (HCO_3^-) excretion, as well as the increased concentrations of protein anions (such as phosphate and albumin). These processes allow the continued increase in V_E (and thus improved acclimatization) to progress throughout this period.[21,22]

The pulmonary circulation is also modulated at altitude. In response to the reduced PAO_2, hypoxic pulmonary vasoconstriction (HPV) occurs within minutes.[23] The mechanism is a contraction of pulmonary smooth muscle cells. This process is independent of any external regulation and has been demonstrated in the laboratory setting in pulmonary smooth muscle cells completely isolated from all other tissues.[24] The exact mechanism of oxygen sensing is a source of ongoing research, but it is known that the smooth muscle contraction itself, as in other tissues, relies upon a rise in intracellular Ca^{2+}. Although the contraction occurs in isolation, it is modulated by both the endothelium and systemic factors such as sympathetic activation. The process is biphasic in nature, with an initial contraction reaching its maximal effect between 2 and 15 minutes. A secondary phase occurs between 30 and 60 minutes, causing further vasoconstriction in sustained hypoxia. This secondary phase appears to be dependent on the presence of endothelial cells.[7,24]

In contrast to HPV in localized hypoxia (as seen in many pathologies found at sea level, such as pneumonia, atelectasis) where this response is beneficial for correcting ventilation-perfusion (V/Q) mismatch, the global alveolar hypoxia seen at high-altitude HPV can be significantly deleterious. Widespread vasoconstriction increases pulmonary vascular resistance 50% to 300%,[23] with a consequent precipitous pulmonary arterial pressure (PAP) increase that may be responsible for altitude-specific pathologies such as high-altitude pulmonary edema (HAPE) (see later in this chapter).[7] This rise in PAP is further exacerbated by physical exercise with chamber studies reporting a PAP of 54 mm Hg on maximal exercise at a P_B equivalent to 7620 m.[25]

RENAL AND ENDOCRINE CHANGES

Renal responses play a key role in altitude acclimatization and have long been observed. The hypoxic diuretic response (HDR) was first observed in 1944.[26] It is characterized by both natriuresis and diuresis and is seen in humans and many other mammals.[27,28]

The earliest phase of the HDR occurs within hours of ascent and is in fact a diuresis alone, with a static fractional sodium clearance. Hypoxia and hypocapnia appear to be the driving factors (although the exact mechanism remains uncertain)[29] and natriuresis soon follows. During the HDR, a total water loss of approximately 3 L is possible during initial exposure[30] and a decrease of approximately 40% plasma volume.[11]

A number of studies suggest that HDR undergoes humoral regulation.[31,32] The renin-angiotensin-aldosterone system is one of the major systems regulating fluid balance at sea level. Renin and aldosterone promote retention of both water and sodium. However, although renin activity and aldosterone levels are observed to decrease in response to altitude,[28,33,34] this response has not been consistently shown to be directly related to the level of natriuresis observed, suggesting there may be a mediation driven by chemoreceptor activation.[28] It is also of note that although the aldosterone exercise response (leading to an increase in plasma aldosterone) remains present at altitude, it appears to be reduced.[33] Indeed, further elements of the hormonal response also appear inconsistent. An increase in serum osmolality is reported with altitude ascent and although this may be expected to produce a concomitant increase in arginine vasopressin (AVP), such a response is often not observed, suggesting a change in AVP regulation at altitude in favor of a diuresis.[35-37]

The other side of the coin, from a fluid homeostasis perspective, is atrial natriuretic peptide (ANP). It is produced by cardiomyocytes in response to atrial distension and plays an important role in fluid balance; an increase in ANP will induce a natriuresis.[38] It has been observed to increase in response to both pure hypoxia and altitude ascent and may play an important role in the initial diuresis,[34,38,39] although any direct causal relationship between ANP levels and the observed diuresis/natriuresis have been questioned.[28]

Although controversy remains around the exact relationship between any hormonal changes and the observed diuresis/natriuresis, a number of studies have reported an association between a picture of increased fluid retention, or hormonal changes promoting fluid retention, and altitude pathologies such as acute mountain sickness (AMS) and HAPE.[34,40] This suggests that, regardless of the underlying regulation, diuresis remains an important part of successful acclimatization.

In addition to fluid balance, the renal system is also important in mitigating the pH changes generated by the HVR, as discussed previously. Urinary bicarbonate excretion increases over a period of hours to more than 2 weeks, in a process that appears to be unrelated to the natriuresis previously discussed.[41] This reduces blood pH, and may play a role in facilitating the ongoing increase in V_E and, therefore, acclimatization to altitude.

Additional endocrine changes may also be observed following altitude exposure. Cortisol, a stress hormone secreted by the adrenal glands, appears to increase at altitude,[33,42,43] although exceptions are found in the literature.[44] It may be that this variation is related to duration of exposure, exercise state, and other stress factors, such as coexisting pathology.[37]

As previously discussed, sympathetic activation forms an essential part of the response to acute altitude exposure, which drives many other physiologic changes. As expected, levels of norepinephrine and epinephrine increase,[42,45] as does nerve fiber activity.[46] However, after prolonged exposure and despite persistently elevated catecholamine levels, maximal HR and response to chronotropic drugs (e.g., isoprenaline) are both reduced, which suggests that a degree of desensitization is also occurring.[47]

CENTRAL NERVOUS SYSTEM

Several central nervous system (CNS) changes are found at high altitude. Many of the most frequently observed were eloquently described by John West, one of the leading figures in respiratory and high-altitude physiology.

> *On ascending to altitude, unacclimatized lowlanders typically complain that they take longer to get to sleep, wake frequently, often have unpleasant dreams and do not feel refreshed in the morning. The resultant difficulties are not confined to the night because, as a result of poor sleep, people often feel somnolent and fatigued during the following day, their productivity is reduced and they are more liable to make errors.*[48]

This quote encapsulates two separate changes observed at altitude: sleep disturbance and cognitive changes.

Sleep disturbance is a frequently occurring symptom, with incidences of up to 65% reported on ascent.[49,50] Indeed, a network analysis of symptom scores in altitude sojourners identified the largest single cluster of symptoms to be one primarily characterized by sleep disturbance.[51] Subjectively, individuals report reduced general sleep quality, difficulty in falling asleep, frequent wakening, as well as temperature-related discomfort.[52]

At high altitude, the sleep architecture is altered. The duration of light sleep, and non-rapid eye movement (NREM) sleep stages I and II, is increased. Deep sleep and NREM stages III and IV are reduced dramatically,[53-55] whereas rapid eye movement (REM) sleep duration appears to be more variable in duration.[54] Frequent awakenings are also observed, which appear to be closely linked to another phenomenon seen during sleep at altitude: periodic breathing.[53,55,56]

Periodic breathing, as described by John Cheyne and William Stokes in the 19th century and named eponymously for them,[57,58] has long been observed at altitude. Reports date back as early as 1857 before it was first described fully by Angelo Mosso in 1894.[59,60] Characterized by periods of crescendo-decrescendo hyperpnea followed by apnea at altitude, periodic breathing is seen most commonly during NREM stages I and II and appears to be largely absent during REM sleep.[54] Periodic breathing may be responsible for the frequent awakenings seen at altitude that often occur at the transition from apnea to hyperpnea.[53]

This breathing pattern is caused largely by hypocapnia, which is itself a result of HVR. Although this hypocapnia during wakefulness does not adversely affect patterns of breathing during sleep, both the rate and depth of respiration can decline, culminating in apnea. During this apnea, the partial pressure of carbon dioxide (PCO_2) increases as PO_2 falls, ultimately leading to a return of ventilation with hyperpnea.[55] This theory is supported by the observation that those who demonstrated the most brisk HVR also experienced the highest rates of apnea,[61] along with the efficacy of supplemental oxygen to improve sleep quality.[62] Periodic breathing tends to increase with ascent[55] and may even occur during REM sleep at extremes of altitude.[63]With acclimatization, periodic breathing can be seen to decrease.[54]

The previous quote from John West also alludes to cognitive changes, which are frequently observed at altitude. Studies have demonstrated deficits across a wide range of domains under hypoxic conditions including arithmetic, memory, language, and motor skills.[64-67] In addition to direct cognitive impairment, there are adverse changes in mood state and even new onset anxiety disorders secondary to high altitude.[68,69] The exact etiology of these cognitive changes has not been fully elucidated, although fatigue does appear to be correlated with a number of cognitive domains, and as such, sleep disturbance may be contributory.[70]

GASTROINTESTINAL

On ascent to altitude, anorexia is frequently observed but not fully understood.[71,72] Leptin, a hormone with elevated levels that are associated with satiety, has been hypothesized as playing an important role but the literature is conflicting; elevated, reduced, and unchanged levels have all been reported.[42,44,73,74] Cholecystokinin, another satiety hormone, has been less widely studied but has been found to be elevated, particularly in those with marked anorexia at altitude.[75]

In concert with anorexia, weight loss of both fat and muscle occurs in response to prolonged exposure.[73,76,77] This may be related primarily to reduced intake,[78] although a modest increase in basal metabolic rate is observed, and may be partly attributable to sympathetic drive.[79]

Altitude Illness

Several distinct pathologies are observed in association with both acute and chronic altitude exposure. Although each is considered separately here, some share pathologic features. In addition, the hypoxic environment can also affect individuals with other ongoing health considerations, such as comorbidity or pregnancy.

ACUTE MOUNTAIN SICKNESS

AMS is the most common acute altitude pathology. It is a clinical syndrome of nonspecific symptoms, occurring on ascent to altitude (>2500 m). The onset is usually seen between 4 and 12 hours after ascent.[80-82]

The prevalence of AMS is closely linked to altitude attained—approximately 25% at moderate altitude (<3000 m)[50] and approximately 50% above 4000 m.[83] Other factors exerting a strong influence are rate of ascent, degree of acclimatization, and individual susceptibility.[84] It is relevant to note that physical fitness appears to confer no risk reduction.[85,86] Physical exertion at altitude may increase risk, although studies remain conflicted.[85,87,88]

The pathophysiology of AMS is not yet fully understood. A number of theories have been suggested and current opinion appears to favor CNS dysfunction as the primary cause.[80,81,89] Imaging studies in moderate-severe AMS have suggested some degree of cerebral edema,[89] and increased intracranial pressure (ICP) has also been observed.[80] In one remarkable study by Brian Cummins in 1985, three individuals, including Cummins himself, were fitted with invasive telemetric ICP monitoring. On ascent, two subjects remained well but one developed symptoms of AMS, including headache. This individual was also the only subject to demonstrate a raised ICP. The symptoms were seen on minimal exertion; turning his head increased ICP from 14 to 24 mm Hg, and a press up led to an ICP of 51 mm Hg.[90] This study has never been, and is unlikely to be, replicated but suggests elevated ICP may be pathologically significant and potentially related to reduced intracranial compliance.[81,89,90] Cerebral blood flow (CBF) is known to increase transiently on ascent[91] and, although wide interindividual variations have been observed, it may play a role. A unifying hypothesis has been proposed whereby hypoxia and hypoxemia result in increased CBF, which alongside changes in blood-brain barrier permeability, leads to brain swelling. Finally, in those with reduced intracranial compliance, this leads to AMS.[92] This hypothesis, however, remains speculative, with some believing venous outflow may be more significant than intracranial compliance.[80,93]

The diagnosis of AMS is clinical. The symptoms are variable in presentation but may include headache, nausea, anorexia, dizziness, sleep disturbance, and fatigue.[80,81] Headache is the most frequently observed indication and remains a mandatory symptom for diagnosis in a number of research tools.[82,94] Several scoring systems[51,82,94-96] of AMS exist for research purposes. A number of these have been applied to clinical practice, although they are not validated formally for this use. The most widely used, the Lake Louise Score,[82] is ubiquitous in the literature and consists of five simple, self-reported symptom-related questions. This scoring system was revised in 2018[94] with the removal of sleep disturbance after studies suggested that it is likely to be a separate phenomenon unrelated to AMS (Table 74.1).[51,97] Laboratory testing and clinical examination in AMS are both unremarkable.[81] Oxygen saturation (SpO_2) monitoring has been suggested as a useful tool but although SpO_2 is seen to fall with ascent, there appears to be no independent relationship with AMS.[98]

Optimal clinical management of AMS begins with prevention. The most significant measure should be a slow ascent, with a limit of 300 m gain in sleeping altitude per day at altitudes above 3000 m generally accepted as best practice,[80,89] although 600 m is proposed as an alternative.[80,81] The sleeping altitude is generally accepted to be the most important consideration and the mantra of "climb high, sleep low" can be found widely in the literature. Other nonpharmacologic measures suggested, with some evidence, include: preacclimatization, avoidance of exercise, adequate hydration, and oxygen supplementation.[81,89] Pharmacologic prophylaxis has been widely studied with acetazolamide the most recommended at an adult dose of 125 mg twice daily.[99] Higher doses of acetazolamide remain efficacious; however, they may be associated with more deleterious effects.[100] Dexamethasone (2 mg every 6 hours

TABLE 74.1 Lake Louise Consensus on Acute Mountain Sickness 2018

2018 Lake Louise Acute Mountain Sickness Score

Symptom	Description	Score
Headache		
	None at all	0
	A mild headache	1
	Moderate headache	2
	Severe headache, incapacitating	3
Gastrointestinal symptoms		
	Good appetite	0
	Poor appetite or nausea	1
	Moderate nausea or vomiting	2
	Severe nausea and vomiting, incapacitating	3
Fatigue and/or weakness		
	Not tired or weak	0
	Mild fatigue/weakness	1
	Moderate fatigue/weakness	2
	Severe fatigue/weakness, incapacitating	3
Dizziness/light-headedness		
	No dizziness/light-headedness	0
	Mild dizziness/light-headedness	1
	Moderate dizziness/light-headedness	2
	Severe dizziness/light-headedness, incapacitating	3
AMS Clinical Functional Score		
Overall, if you had AMS symptoms, how did they affect your activities?		
	Not at all	0
	Symptoms present, but did not force any change in activity or itinerary	1
	My symptoms forced me to stop the ascent or to go down on my own power	2
	Had to be evacuated to a lower altitude	3

From Baillie JK. Lake Louise Consensus on Acute Mountain Sickness 2018. In: altitude.org. Apr 2019 [cited 16 Apr 2019]. Available: http://www.altitude.org/lake_louise_AMS_score_2018.php

or 4 mg every 12 hours) has also been shown to be beneficial,[49,101] but remains a second-line chemoprophylaxis.[100] Individual risk is highly variable based on both personal (e.g., previous history of AMS or High-Altitude Cerebral Edema [HACE]) and environmental (e.g., rate of ascent, highest altitude attained) factors. Prescribing of prophylactic medications and indeed any recommendations regarding individuals should consider this personalized risk.

When treating AMS, because of the nonspecific nature of the symptoms, consideration must be given to other causes. There may be more severe altitude pathologies such as HACE, or common conditions related to the nature of much travel to altitude such as dehydration, exhaustion, hypothermia, hypoglycemia, or infection.[100] In cases where AMS is diagnosed, then the single most efficacious treatment is descent. This may present other dangers, given the terrain often found in the high altitude environment; however, in severe cases, descent until resolution of symptoms (which typically occurs after a descent of as little as 300 m) remains the gold standard treatment.[100] Measures aimed at correcting hypobaric hypoxia, such as supplemental oxygen and hyperbaric chambers, can offer possible alternatives to descent but in a remote high-altitude setting these treatments present marked logistical challenges, may only offer temporary benefit, and also carry their own risks.[100,102] Dexamethasone has been shown to be an effective treatment,[102-104] but it does not aid acclimatization and further ascent is not recommended until the patient is asymptomatic without dexamethasone.

HIGH-ALTITUDE CEREBRAL EDEMA

HACE is a severe, life-threatening pathology. It is rare, with a prevalence of 0.28% to 1%.[4,105] Because of its rarity, there is limited systematic evidence regarding risk factors.[81] However, (not yet conclusively proven) HACE is now considered to be a severe form of AMS and may share the same pathophysiology and risk factors.[89,93,106] It is important to note though that while AMS may rapidly progress to HACE if left untreated, HACE may also present suddenly without any preceding symptoms of AMS.

Both animal studies and postmortem examinations have demonstrated gross edema in HACE sufferers,[107,108] with magnetic resonance imaging (MRI) studies suggesting this is likely vasogenic in nature.[109] In contrast to AMS, in HACE there is evidence of microhemorrhage, primarily within the corpus callosum. The presence of microhemorrhage may indicate venous obstruction as a key pathologic process, which may differentiate AMS from HACE.[93]

HACE may be clinically differentiated from AMS by the presence of ataxia, confusion, psychiatric changes, or altered consciousness that may progress rapidly to coma and death.[81,89,93,110] Investigations offer limited benefit on acute presentation; however, lumbar puncture may reveal elevated ICP,[111] whereas MRI and computed tomography may reveal changes associated with edema.[109]

Prevention of HACE should be guided by the same principles as AMS, with slow ascent, preacclimatization, and pharmacologic strategies as previously described.[100] The diagnosis should consider other possible causes for the observed presentation, but it is important to remember the mantra that any illness at altitude should be treated as altitude-related until proven otherwise. When HACE is diagnosed, its severity should not be underestimated and prompt management is essential. Immediate actions include supplemental oxygen (aiming for an $SpO_2 > 90\%$), administration of dexamethasone (initial dose of 8 mg by mouth, or intravenous or intramuscular injections; and immediately followed by a dose of 4 mg every 6 hours) and, where logistically possible, descent.[81,100] If descent is not possible, and the airway is adequately protected, then a hyperbaric chamber is an acceptable temporary alternative.[81,93]

High-Altitude Pulmonary Edema

HAPE is a form of noncardiogenic pulmonary edema that occurs in unacclimatized individuals on ascent to altitude (>2500 m).[81] The condition was first described in South American lowlanders on ascent to altitude in 1955,[112] and subsequently in 1960 by two separate American physicians.[113,114]

The condition generally occurs within 2 to 5 days of ascent and is more common with greater altitude. It remains relatively uncommon under 3000 m and after more than 1 week at altitude.[115,116] As with many altitude pathologies, the rate of ascent, altitude, and individual susceptibility are the most significant risk factors for the development of HAPE.[7] There is evidence of other predisposing factors including: male sex,[117] preexisting respiratory infection,[118] and cold temperatures.[119] Cardiorespiratory diseases, including anatomical abnormalities affecting pulmonary blood flow, have also been shown to increase risk of HAPE and it should be noted that altitude dwellers may suffer from "re-entry" HAPE following a sojourn to lower altitudes.[115] The prevalence of HAPE varies greatly depending on the aforementioned risk factors. For example, in the general population prevalence of HAPE is estimated at less than 0.2% when climbing to 4500 m in 4 days. However, for a 1- to 2-day ascent to the same altitude, the prevalence rises dramatically to 6%. In those with a known susceptibility to HAPE, this could reach as high as 60%.[116]

The pathophysiology of HAPE is closely related to HPV and the increase in PAP. Pulmonary hypertension is seen on ascent to altitude prior to the development of HAPE.[120] Individuals who are susceptible to HAPE tend to have a brisk HPV response, and often a relatively blunted HVR which further drives HPV. This accentuated rise in PAP of approximately 60 mm Hg in untreated HAPE on ascent may also be partly related to decreased nitric oxide (NO) bioavailability.[121] The subsequent edema appears to be directly related to this increase in pressure, with bronchoalveolar lavage in early HAPE showing little inflammatory change, while pulmonary capillary pressure exceeds values shown in animal models to cause edema.[121]

Early clinical presentation is most commonly exertional dyspnea, often associated with a dry cough. This results in reduced exercise performance. Dyspnea is normally progressive, leading to dyspnea at rest, while the cough may become productive of pink frothy sputum—with hemoptysis of frank blood being rare.[115] Orthopnea is additionally seen as edema progresses. Symptoms of AMS may coexist, but around 50% of sufferers display none.[117] Examination findings typically include tachycardia and tachypnea. Cyanosis may be present and, although not universal, crepitations are invariably audible on auscultation of the lungs.[7] SpO_2 and blood gas analysis show more profound hypoxia than in healthy controls, while radiographic findings demonstrate patchy edema, generally starting peripherally.[122]

As with AMS, if appropriate steps are taken, the incidence of HAPE can be significantly reduced. Gradual ascent remains the single most effective means of reducing HAPE occurrence.[100] Individuals with a history of HAPE should take additional care and in such cases pharmacologic prophylaxis may be warranted. Nifedipine, a calcium channel blocker, has been shown through randomized control trial[120] and clinical experience[100] to be effective in high-risk individuals, delivering significantly lower PAP and improved prophylaxis of clinical HAPE over a placebo. Other medications, such as salmeterol[123] and tadalafil,[124] have shown promise in clinical trials but clinical experience remains limited. Further research is required, although salmeterol is considered as an adjuvant to nifedipine in high-risk cases.[100] Dexamethasone, which is used widely in AMS/HACE, is not as regularly utilized in HAPE. There is some data supporting its use,[124] but again further study is advised to confirm.[100]

As with AMS/HACE, descent remains the most effective treatment for HAPE. Improvements may be seen after only minimal descent, although descent of 1000 m or until symptoms resolve is advocated. The degree of exertion on descent should be minimized as much as possible to reduce further rise in PAP.[100] Supplemental oxygen and hyperbaric chambers are further measures to consider when descent is not possible. Nifedipine continues to have a role in treatment, with a single unblinded trial showing some clinical improvement[125] and extensive clinical experience supporting its role.[100] Phosphodiesterase inhibitors and dexamethasone may both confer some benefit and case reports of their use exist.[126,127] It is important to point out that unlike other forms of pulmonary edema, the use of diuretics is not advocated in HAPE, particularly as patients may have concurrent hypovolemia.[100] In the hospital setting it may be possible to manage HAPE without descent using supplemental oxygen and close observation. The use of continuous positive airway pressure has been advocated but remains unreported.[100]

CHRONIC MOUNTAIN SICKNESS

Chronic mountain sickness (CMS), also known as Monge disease, is a syndrome affecting lifelong altitude dwellers and native populations. First described by Carlos Monge in 1928 in Peru,[128] it is characterized by excessive erythrocytosis (EE), which may lead to pulmonary hypertension, cor pulmonale, and congestive cardiac failure.[129]

CMS prevalence varies widely among high-altitude populations around the world. Tibetans have a low prevalence with 1.2% reported, while with the Han Chinese in the same region the rate is 5.6%. The rates in South America are also generally higher with a prevalence of 4.5% in the general population,[130] and increasing up to 33.7% in miners 60 to 69 years of age.[131] These ethnic variations may be explained by significant differences in adaptation to high altitude. Tibetan natives have been dwelling at altitude for significantly longer than Andean natives and have adapted very differently. Andeans show lower HVR and stronger HPV than Tibetans and even in health show a preponderance for higher Hb than is observed in Tibetans.[5] Other than ethnic variation, there appears to be a direct correlation with altitude; a study in North India observed no cases of CMS below 3000 m, yet a prevalence of 13% above this elevation.[132]

The underlying cause of the EE is not yet fully understood. It is generally accepted that chronic hypoxia, potentially exacerbated by a loss of ventilatory acclimatization leading to central hypoventilation, results in an erythrocytosis. The EE may be mediated by EPO, which is produced in response to hypoxia; however, the correlation between EPO levels, SpO_2, and Hb is not consistent, suggesting that it is not the sole factor.[129] Recent gene studies have highlighted the potential role of SENP1, a gene involved in EPO regulation. Individuals with CMS SENP1 appear to show a higher transcriptional response to hypoxia[133-135] and the gene is the subject of ongoing research in this field.

Clinically, CMS may be identified by the excessive erythropoiesis (females Hb ≥19 g/dL; males Hb ≥21 g/dL) and severe hypoxemia.[136] Symptoms of this include headache, dyspnea, fatigue or sleep disturbance, and a burning sensation in the hands and feet. Meanwhile, signs include cyanosis (particularly marked in mucous membranes), finger clubbing, and dilatation of blood vessels. Further investigations may demonstrate pulmonary hypertension and cardiac failure. Of clinical relevance are family history, obesity, and sleep apnea, which are all risk factors for the development of CMS. The gold standard tool for diagnosis is the Qinghai score for CMS.[136] It is important to note that the diagnosis of CMS should only be made in the absence of other systemic disease that may explain hypoxemia, such as chronic airway diseases.

The optimal management of CMS is permanent relocation to a lower altitude; however, CMS will dissipate with the resumption of normoxia. When permanent relocation is not possible, sojourns to lower altitudes may help to stop Hb from hitting excessive levels.[129] Venesection, with or without isovolumetric hemodilution, is used widely in clinical practice.[129,136] However, supportive literature is of limited quality[137,138] and there are concerns about a rebound effect on Hb, although these are unproven.[129] In addition, recent evidence suggests that iron deficiency caused by venesection may worsen pulmonary hypertension and advocates the use of iron supplementation to ameliorate this effect.[139] Numerous pharmacologic compounds have been studied with limited success including: ACE inhibitors, ventilatory stimulants, and dopaminergic antagonists. Recently, more focus has been given to acetazolamide with positive results, suggesting it is safe, able to reduce erythrocytosis, and improve pulmonary circulation, although side effects associated with long-term use remain unknown.[140,141]

COMORBIDITY AT ALTITUDE

The acute altitude pathologies described previously have been largely studied in healthy populations and there is a limited body of evidence to characterize how existing disease may be affected by ascent to altitude.[142] At the same time, travel to remote, high-altitude destinations is becoming easier, and people are living longer with a higher burden of chronic disease[143]; as a consequence, the challenges of managing chronic disease at altitude are likely to become increasingly relevant.

It is recommended that individuals with significant preexisting disease should consult an experienced altitude physician and undergo a risk assessment before travel. The assessment should consider existing conditions as well as details of the proposed trip, including ascent profile and level of exertion.[144] The conditions most likely of concern at altitude are those affecting the cardiorespiratory system because these may cause additional difficulty in adapting to the hypoxic environment. Consideration should be given to two separate issues: whether chronic disease will predispose individuals to the development of acute altitude pathologies and whether altitude exposure will exacerbate chronic disease.[142]

Ischemic heart disease is a pathology that may be worsened by altitude exposure. Acute altitude exposure increases cardiac output, and thus myocardial oxygen demand, while in the presence of reduced arterial oxygen content.[145] Estimates of myocardial perfusion in healthy subjects suggest that there may be some reduction at altitude, which may be partly ameliorated by acetazolamide.[146] However, several studies have exposed patients with stable coronary artery disease (CAD), who are deemed to be low risk and who have exercised at altitude with no adverse effects.[147,148] A single study of eight patients with moderate-risk disease demonstrated that compensatory mechanisms of coronary circulation may be exhausted at even moderate altitude.[149] Current recommendations advise cautious ascent to a maximum of 4200 m by low-risk patients, who have had a minimum of 6 months postmyocardial infarction or revascularization before travel. These recommendations also advise moderate-risk patients not to ascend above 2500 m, with only light exercise undertaken, while those at highest risk should avoid altitude entirely. Consideration should be given to acetazolamide, as it may aid coronary perfusion, but this has not been verified in patients with CAD.[145]

Patients with heart failure may pose a significant challenge at altitude, particularly as the condition is often closely linked to other comorbidities. However, studies on patients with stable disease (New York Heart Association Class II-IV) have demonstrated moderate altitude may be tolerated without significant compromise, although those with the most severe disease were significantly limited in their exercise tolerance.[150,151] Medications used to manage heart failure should also be closely reviewed. Use of diuretics must be monitored, as fluid status is likely to alter at altitude and particular care should be paid to concomitant use of acetazolamide. Studies suggest that selective β1 receptor antagonists may improve exercise performance when compared to nonselective beta blockers and are advised where practical.[145,152] In summary, those with the most severe disease should abstain from travel to altitude whereas those with mild to moderate disease should proceed with caution.[145]

In the presence of the hypobaric hypoxia found at altitude, there is concern for exacerbation of respiratory disease. Counterintuitively, however, observational data suggest that asthma is less common, and less severe, in those living at altitude.[153,154] One likely reason for this is the reduced population of dust mites at altitude secondary to the cold, dry, and hypoxic conditions[155] that result in a significant improvement in many pathologic features of asthma.[156] However, such studies do not provide evidence regarding acute altitude exposure. There have been a number of observational studies exploring acute altitude exposure[157-160] with conflicting results for physiologic measurements (e.g., peak expiratory flow, forced expiratory volume in 1 second [FEV1]), but all have demonstrated safe travel for patients with mild asthma to altitudes of up to 6410 m. Caution is advised, however, as upper airway infections, particularly in remote environments, remain a risk for asthmatic patients.[161] Hence, while travel to altitude is safe for well-controlled asthmatics, adequate supplies of rescue inhalers and oral steroids are advised.[142] Measures may also be taken to limit cold, dry air exposure, which often exacerbates asthma.[157] These can be as simple as covering the nose and mouth during outdoor exposure.[142] Those with poorly controlled or severe asthma are at high risk because of the remoteness of the environment and variability of medical facilities, and travel should be avoided where possible in this group.[142]

Chronic obstructive pulmonary disease (COPD) poses a particular challenge at altitude. Studies of altitude dwellers with COPD demonstrate increased mortality and cor pulmonale.[162,163] A number of studies simulating altitude as a model for commercial air flight have shown marked hypoxemia in response to moderately simulated altitude.[164,165] A similar drop in PaO_2 was observed in mild to moderate COPD sufferers on ascent to 1920 m, with a mean PaO_2 fall from 8.8 kPa at sea level to 6.9 kPa.[166] However, no adverse clinical events were reported in these studies and, given the chronic nature of the hypoxia, there is likely to be some degree of preexisting adaptation.[142] Particular care must be taken in COPD patients with pulmonary hypertension. As previously discussed, the pathophysiology of HAPE indicates that preexisting pulmonary hypertension may increase susceptibility to HAPE.[142] When assessing risk of hypoxemia at altitude, the use of formulae derived to predict PaO_2 during flight may be helpful.[167] In general, there are limited data on the safety of travel to altitudes for patients with COPD, and no data for their travel above 3048 m. Patients with COPD, and in particular those with pulmonary hypertension, should seek medical advice prior to traveling to high altitude.

Special Situations at Altitude

CHILDREN

Children represent an understudied group at altitude. While many of them either live at or sojourn to higher elevations, comparatively few studies have examined this. Children born and living at altitude are at increased risk of hypoxemia either secondary to acute pathology or congenital abnormalities. However, the risk and responses to living at altitude vary greatly among different ethnic populations as a result of the variations in adaptation as previously discussed.[168]

Studies on acute exposure to altitude suggest that children show similar patterns of acclimatization as adults.[169,170] Altitude pathologies meanwhile present a significant problem in children. A study in Colorado at 2835 m estimated a 28% prevalence of AMS in children.[171] However, the diagnosis of AMS remains problematic in children, as many symptoms of AMS may be associated with any travel in children. The same holds true for more serious altitude pathologies of HAPE and HACE, which may be overlooked in children (especially of younger age). As a result, extreme caution and descent is advised when a child becomes unwell at altitudes above 2500 m.[172] Pharmacotherapy is less widely advocated in children, particularly for mild cases of AMS. In severe cases or where HAPE develops, there may be a place for weight-appropriate doses of acetazolamide or nifedipine.[173]

PREGNANCY

Maternal hypoxia may develop as a consequence of travel to high altitude (>1800 m) with obstetric guidelines identifying this as potentially hazardous for the fetus,[174,175] although evidence suggests a number of pregnant women will travel to altitude.[50,176] There are limited data available on this subject, with only a small number of studies exploring on sojourners to altitude.[176,177] There is evidence of an increased rate of neonatal intensive care admission and oxygen administration at birth in infants of altitude residents.[176] In addition, multiple population studies demonstrate a significant reduction in birth weight that is proportional to altitude gain above 2000 m. This is not due to increased prematurity but rather intrauterine growth restriction (IUGR).[178,179] The effect of altitude on birthweight in these populations varies among different populations. It is more pronounced in recently arrived populations, such as the Han Chinese and Europeans, and least pronounced in groups such as Tibetans, who have resided at altitude for much longer.[1] This suggests any results derived from sojourners or permanent residents are unlikely to be entirely transferable.

The limited number of physiologic studies on the fetal effects of maternal hypoxia suggest changes in the placental villous membrane facilitate increased gas exchange.[180] With these changes, the fetuses of women exposed to short administrations of 10% oxygen show no signs of distress with no significant change in fetal heart rate, HR variability, or Doppler velocimetry in the umbilical artery.[181] However, studies on altitude dwellers have demonstrated a reduction in the pregnancy-associated increase in uterine artery blood flow,[182] which may account for IUGR.

Additional research is required in this field and the paucity of evidence makes any firm recommendation challenging. There are clear physiologic sequelae for both mother and fetus in response to altitude, which in the chronically hypoxic mother appear deleterious. Consequently, any travel to altitude during pregnancy must be with caution, although conclusive data for sojourners are unavailable.

Anesthesia at Altitude

GENERAL PRINCIPLES

Most surgical facilities are not situated at extremes of altitude. However, a number of centers perform operations at high altitude,[183,184] while at any altitude there may be an emergent need for general anesthesia.[185] Practice under these conditions is guided largely by clinical experience, the setting, and select published case reports.

The anesthetic practitioner at altitude should be aware of the physiologic and pathologic changes, discussed previously, which may affect individuals. They should endeavor to assess on an individual basis how these changes can impact each patient. Consideration should be given to the altitude at which anesthesia is performed, the level of acclimatization of the individual, and any concomitant pathology. When logistically feasible, it may be advisable, particularly in unacclimatized individuals, to descend before administration of anesthesia.[186] At extremes of altitude, the risks associated with anesthesia are only outweighed by life- or limb-saving procedures.[185]

It is also important to establish the environment in which anesthetisa will take place. The operating environment in a hospital with formal operating theaters and associated equipment is very different to emergency surgery undertaken in a remote and rural setting, regardless of altitude.

Several aspects require particular consideration, the most obvious of which is the increased risk of perioperative hypoxia. Medications used during anesthesia, notably opiates, depress both the tachycardia and tachypnea associated with the physiologic response to altitude.[186] Slowed recovery from anesthesia has been reported,[187] as has increased sensitivity to anesthetic medications.[185] These factors combine to create a prolonged period where an individual may not be able to enact the full range of compensatory mechanisms to tolerate hypobaric hypoxia. Some of these consequences may be reversed by the administration of supplemental oxygen[187] and certainly oxygen therapy at altitude is advised when possible.[186] Care with analgesic agents in the postoperative period is necessary to ensure ventilation and oxygenation is not compromised; analgesia-induced respiratory depression was implicated in the death of a Sherpa who underwent a debridement at 4300 m.[188]

The second area of particular note in the perioperative period are reports of increased bleeding and challenging hemostasis during surgery at altitude.[183,187] This is attributed to increased venous pressure and increased capillary density[186] and, while not conclusively proven, still warrants consideration.

ANESTHETIC EQUIPMENT

The most routinely considered implication of high altitude on anesthetic equipment is in relation to anesthetic vaporizers. As variable bypass vaporizers rely on the saturated vapor pressure of anesthetic agents, the partial pressure of anesthetic gas delivered remains constant regardless of altitude, although the Fi_{AA} will rise. This should in theory mean the same clinical effect.[189] Chamber-based studies on vaporizers have confirmed a constant partial pressure delivery;[190] however, several caveats to this exist. First, desflurane vaporizers operate by using a measured flow principle.[189] Such vaporizers will deliver a constant Fi_{AA} and, therefore, in hypobaria will deliver a reduced partial pressure. Second, consideration must be given to the monitoring and targeted dose of anesthetic gas. The minimum alveolar concentration is often used to guide dosing of anesthetics but it is not appropriate for use at altitude. Instead, practitioners should consider their administration as a partial pressure rather than a fraction, or concentration, as it is the partial pressure that determines depth of anesthesia.[191] This is most apparent when considering nitrous oxide, which when delivered at a given concentration is less effective at altitude, proportional to the drop in partial pressure.[192]

This recommendation regarding the use of partial pressure should also be considered for all forms of gas monitoring. Modern anesthetic machines may interchangeably state partial pressure or concentrations for gas monitoring.[191] However, the analyzers themselves physically detect partial pressure, not concentration. The reported concentration is derived mathematically and, for example, an oxygen analyzer set to measure 21% in air at sea level will read 17.4% in air at 1500 m, unless recalibrated.[190] Once again, the physiologic significance is in the partial pressure of oxygen. Therefore, direct measurement of partial pressure allows greater understanding of the physiologic effect of the gas mixture being delivered to the anesthetized patient.[191]

Flowmeters are also affected at altitude. Flowmeters rely on the density of gas to measure flow. Studies examining the floating flowmeters showed that with reducing P_B, and therefore density of gas, these flowmeters were liable to be under-read.[190] The percentage of error observed was not constant but reached a peak error of 21%, making adjustments challenging. Studies have not been conducted to observe the impact of high altitude on flowmeters found in more modern anesthetic machines such as hot wire anemometers. Caution is advised when examining readings from flowmeters and where possible gas analyzers directly measuring partial pressure should be used to corroborate.

GENERAL ANESTHESIA

Several considerations for anesthesia at altitude have already been discussed, including perioperative hypoxia and the effects of anesthetic drugs on mechanisms of acclimatization. As such, when considering anesthetic agents, the maintenance of these mechanisms, including tachycardia and hyperpnea, may be desirable. This is particularly relevant in the austere environment where supplemental oxygen may not be available. In such environments, the use of ketamine has been advocated in both emergency[185] and elective[193-196] settings. These reports have varied in their approach, with some using entirely ketamine anesthesia, whereas others have supplemented with inhalational anesthesia or benzodiazepines. Without supplemental oxygen, some degree of desaturation may be observed in the spontaneously breathing patient, but this was felt acceptable and could be managed with monitoring and simple airway maneuvers.[194] However, total apnea may be seen with smaller doses of ketamine than would be expected at sea level, with a report of deep general anesthesia and apnea at a dose of only 0.5 mg/kg;[185] however, other studies have successfully used higher doses without any adverse outcome.[196] Further caution is advised when using ketamine, as it may increase pulmonary vasoconstriction, with a single study at 1600 m suggesting certain susceptible patients may develop increased pulmonary vascular resistance with ketamine use.[197] This may make it an undesirable agent for use in patients with active, or high risk of developing, HAPE.

Any anesthetic at altitude, particularly emergency remote surgery, remains comparatively high risk because there are limited data on which to base practice. There is some literature suggesting that ketamine may be used safely (either alone or in combination). Adequate monitoring, airway equipment, and appropriately trained practitioners are advised, alongside a careful risk-benefit analysis and consideration of alternative courses of action.

REGIONAL ANESTHESIA

Spinal anesthesia may be desirable at altitude, as it allows the individual to maintain his or her own ventilatory parameters and reduces much of the risk surrounding perioperative hypoxia. Reports of very high rates of postdural puncture headache (PDPH) do exist;[187] however, these predate the use of modern spinal needles with narrower gauges and pencil-point needles now routinely used in modern practice.[198] A single study examining spinal anesthesia at moderate altitude (1890 m) found that at altitude spinal blocks took longer to perform, and block duration was shorter than at sea level.[199] They also observed a higher rate of PDPH (7.14 vs. 2.85%; $P < .05$) at altitude. Despite these limitations, spinal anesthesia provided adequate analgesia for lower extremity surgery in all patients and no significant complications were reported. Based on this limited evidence, spinal anesthesia may be the first choice for such procedures at high altitude but further study is advised.

APPLICATION TO FLIGHT, INCLUDING AIR TRANSPORT OF CRITICALLY UNWELL PATIENTS

The contents of this chapter remain relevant when considering air travel. Cabin pressure in commercial air travel is regulated but studies have shown peak cabin altitudes do vary, with an average value of 1933 m and the highest recorded being 2606 m.[200] The physiologic changes are equivalent to those experienced by visitors to high altitude but with the caveat that ascent happens much more rapidly with less time to acclimatize. A small drop in SpO_2 may be observed, and symptoms of AMS have been reported. Despite this, air travel is generally physiologically well tolerated.[201] Greater concern may be associated with prolonged immobility and the risk of thromboembolic phenomena.[202] In contrast, patients with significant comorbidity may not tolerate air travel because of the rapid altitude gain and relative hypoxia. Extensive guidelines exist to guide the decision on flying with health conditions.[204] In the rare event of cabin decompression, risks are considerably higher. In addition to acute hypoxia, which at altitudes above 13,716 m may induce unconsciousness in as little as 15 to 20 seconds, there are dangers posed by sudden air movement, cold, and debris.[203]

The transfer of an unwell patient is a significant undertaking that relies on careful planning, adequate infrastructure and equipment, and a thorough understanding of the patient's physiology and pathology.[205] In addition to hypoxia, there should be an awareness for gas expansion within body cavities.[205,206] This expansion may affect pathologic processes, such as pneumocephalus, pneumothorax, or intestinal gas, which is particularly significant in cases such as volvulus. The presence of any of these pathologic processes is a relative contraindication for aeromedical evacuation,[205] but the decision must be ultimately be balanced against the need for ongoing treatment not available at the patient's location. Gas expansion also changes the volume of air within medical devices, such as endotracheal cuffs. Ascent to 2500 m from sea level increases the volume in an endotracheal cuff by approximately 35%,[207] which should be considered and accounted for both on ascent and descent. There are additional working challenges related to the enclosed space and moving of patients.[205,207] A large cohort (19,228) of aeromedical evacuations in Canada reports a critical event on 5.1% of evacuations at a rate of 1 per 12.6 hours of transport time.[208] Critical events were more likely to occur in older patients, those with greater hemodynamic instability, and those requiring assisted ventilation. The most common critical event was hemodynamic deterioration and the need for intubation was the most common major resuscitative procedure required. The mortality in the cohort remained very low at 0.1%.[208] These results demonstrate that with appropriately trained practitioners, aeromedical evacuation can be performed safely and with great benefit to patients.

Space Medicine

Atmospheric pressure decreases exponentially with increasing distance from the Earth's surface and becomes progressively hostile to human survival. At the cruising altitude of commercial airliners (approximately 39,000 feet), the atmospheric pressure outside the aircraft is only approximately 20% of the pressure at sea level. The International Aeronautics Federation defines the boundary of outer space, where the Earth's atmosphere stops and space starts, as an altitude of 100 km above the Earth's surface.[209] However, at any particular time, astronauts on board the International Space Station (ISS) are 350 to 450 km above the Earth's surface as they circle our planet at velocities of up to 17,500 mph. Yet, these extreme altitudes are still considered to be relatively low Earth orbits and future astronauts will travel much farther away from the protective environment of the Earth.[210]

INTRODUCTION TO SPACE EXPLORATION AND MEDICINE

On November 5, 2015, the National Aeronautics and Space Administration (NASA) announced it was looking for astronauts for long-duration space flights, including extended missions on the ISS and possible journeys to Mars.[211] In recent times, both the United States and Russia have announced their intentions to construct a new spaceport on the moon and to use this lunar base as a stepping stone to send their own astronauts to Mars. Private billionaire entrepreneurs (such as Richard Branson and Elon Musk) have outlined similar visions and promised to revolutionize air travel by transporting passengers using rockets traveling through space instead of traditional airplanes traveling through the earth's atmosphere. An international "space race" is undoubtedly already well underway.

Technology, skills, and knowledge have all developed rapidly since humans first entered space in 1961 when Yuri Gagarin orbited the Earth for the first time during a flight lasting less than 2 hours in total.[212] Yet since then, only 12 men have ever walked on the moon and over four decades have passed since the last Apollo mission (Apollo 17) left Earth.[211] A future that includes successfully leaving low Earth orbit again and sending astronauts on more distant missions, as well as making spaceflight safe for commercial purposes, poses many challenges, including how best to identify and manage any potential health issues among future crewmembers and passengers.

RISK OF DISEASE AMONG ASTRONAUTS DURING SPACE TRAVEL

Although the absolute chance of a medical issue arising during spaceflight is low, the risk remains significant. Current conceptual plans for future missions to Mars from NASA predict crewed missions lasting up to 1100 days (approximately 3 years).[213] Given the rate of emergencies among the general population is around 0.06 events per year, a crew of 6 astronauts would expect to encounter at least one medical emergency during a 3-year space mission ($0.06 \times 6 \times 3 = 1.08$ events).[214]

Astronauts can be affected by illness or disease just as any other human. For example, concern about possible exposure to the German measles virus meant that NASA Astronaut Thomas K. Mattingly was famously removed from the crew of the ill-fated Apollo 13 mission just 72 hours prior to launch (Mattingly never actually developed measles and went on to successfully fly future missions including both Apollo 16 and STS4).[215] However, the unique environmental conditions associated with spaceflight can also modify an astronaut's susceptibility to such illnesses. Identifying these effects remains an active focus of research, such as the Longitudinal Study of Astronaut Health that NASA has been operating since 1992.[216] This cohort study is generating data about all-cause astronaut mortality and morbidity, such as the reassuring finding that cancer mortality among astronauts is not significantly increased (as might be expected from increased exposure to harmful doses of radiation, as later discussed), suggesting the many preventative measures employed to mitigate these risks during spaceflight appear to be effective.[216]

Similarly, the spaceflight environment can also cause a number of specific health concerns to astronauts that are not normally experienced by the general population and which can affect the physiologic and psychologic performance of crewmembers. One survey of astronauts returning from 79 U.S. space shuttle missions showed that as many as 94% of crewmembers took some form of medication at some stage during the flight and often to treat conditions not normally expected among similarly physically fit cohorts on Earth. These conditions included space motion sickness (SMS), sleeplessness, headache, or backache.[217,218]

The Environmental Challenges Posed by Spaceflight

EXTREME ACCELERATIONS/DECELERATIONS

Takeoff and landing (including re-entry to the Earth's atmosphere) are two of the most important and dangerous periods of any spaceflight. Every human fatality during spaceflight to date (Challenger, Columbia, Soyuz 1, and T11) has occurred during one of these critical periods.[210] Astronauts routinely experience extreme accelerative forces of around 4 to 5 G during takeoff and re-entry but these can be much higher; Yuri Gagarin remained conscious while experiencing forces of around 8 G during re-entry in his spacecraft Vostock 1 in 1961, and the Apollo astronauts typically experienced landing forces of around 17 G and tolerated them remarkably well.[211,212] Current ISS crews returning in Russian Mir spacecraft use seats with specially designed shock absorbers and liners to decrease these forces by 20% to 30% and bring them down below 22G.[211]

These accelerative and decelerative forces are more than capable of dislodging incorrectly stowed items of equipment (causing trauma from the impact of flying objects or hard landings a real hazard), and also generating extreme temperatures from friction with the surrounding air. During re-entry, the outside of the U.S. space shuttle reached temperatures in excess of 15,000°C. This was high enough to ionize air and remove electrons from the outermost atoms on the protective heat tiles around the Shuttle spacecraft surface, generating significant amounts of electromagnetic disturbance that prevented any radio contact with the onboard crew for 17 minutes. On February 1, 2013, damage to one of the heat tiles during takeoff led to a weakness in the Space Shuttle Columbia's critical heat-protective layer, leaving the vehicle unable to withstand these extreme temperatures on its return to Earth and causing the vehicle to burn up on re-entry, resulting in the loss of all seven crewmembers on board.[211]

RADIATION

Solar radiation exposure (i.e., galactic cosmic rays, high-energy photons, high-energy and charge (HZE) neutrons and nuclei, and solar particle events) has always posed a major health concern for astronauts. These risks of both acute (mission-critical) and chronic (post-mission) radiation-related exposure are only going to increase on longer-term exploratory missions deeper into space.[219] Crewmembers have not completely left the protection of the Earth's magnetic field (i.e., gone beyond the Van Allen belts) since the Apollo missions, but crewmembers on any future mission to either the moon or to Mars will be at risk of direct exposure to full solar radiation doses for the first time in over 40 years and currently no adequate shielding strategy has been fully developed and tested.[220] Chronic exposures of less than 1 sievert (Sv) per year are still thought to have long-term effects on tumor rates; acute exposures of 0.5 to 1.0 Sv could be sufficient to cause symptoms of acute radiation exposure. Some estimates predict exposure rates could almost nearly reach such levels during a 940-day Mars mission.[221] Other estimates have even projected radiation exposure levels during a simulated Mars mission, that would for the first time even exceed the strict occupational career limit NASA currently employs (i.e., upper confidence interval [CI] for risk of exposure-induced death [REID] of 3%), using the recommendations by the National Council on Radiation Protection.[222] During a 1-year deep-space mission at minimum average solar radiation levels, the total risk of exposure-induced cancer in a 45-year-old male who has never smoked is predicted to be approximately 2% (CI 0.53%-7.84%), with the risk anticipated to be highest for lung cancer followed by colorectal cancers.[219] However, our overall understanding of the long-term health risks from radiation exposure during spaceflight is still relatively limited and marked differences between current predictions and previously observed effects remain.[223] Besides malignancy, other chronic radiation exposure health risks have been noted among astronauts. For example, increased rates of cataract formation have been reported in those exposed to greater than 8 millisievert (mSv) of radiation after a 20-day space mission,[216,224] reduced fertility (and/or increased numbers of birth defects in animal studies),[211] and a slightly (but not statistically significant) increased risk of developing clinical thyroid disease.[216] Initially, the CNS was thought to be relatively resistant to the effects of radiation; however, widespread CNS changes have been reported including memory impairment, changing synapse plasticity, impaired executive function, and cognitive dysfunction.[225-229] Moreover, many of these effects may be even further compounded by the significant neuropsychologic challenges of spaceflight.

ISOLATION, CONFINEMENT, SLEEP DISTURBANCE, AND OTHER PSYCHOLOGICAL CHALLENGES

Traveling at over 17,000 km/h, the crew of the ISS travel completely around the Earth—what we usually define as a typical "day"—every 90 minutes. This means that in every 24-hour period, the ISS crew experience no fewer than 16 sunrises and 16 sunsets; in other words, crewmembers could easily see 365 sunrises (a whole year's worth) in just a 23-day space mission. The sleep-wake cycle is closely linked to biologic circadian rhythms regulated by the solar light,[230] but astronauts also face many other challenges to sleeping comfortably, such as constant noise, physical discomfort (astronauts usually sleep in sleeping bags fixed tightly to the walls of the space craft), and hypercapnia. Sleep deprivation and fatigue are common complaints among crewmembers, with studies suggesting that on average astronauts experienced just 5.96 hours (SD 0.56) sleep during space shuttle missions, 6.09 hours (SD 0.67) during ISS missions, and less than 6.5 hours during their 3-month pre-launch period.[231,232] Similar levels of sleep disturbance have been reported to impair cognitive performance and worsen long-term health outcomes.[231,233] The constant stresses posed by extreme isolation and prolonged periods of confinement can also increase sleep disturbances and affect individual and team behavioral performances.[234] Interestingly, though, these effects seem much more variable between different individuals and would also appear to be trainable. In the Mars 500 study, 6 males were confined for 520 days in a 550 m^3 chamber simulating a high-fidelity Mars mission. One crewmember reported depressive symptoms throughout 93% of the mission, whereas two other crewmembers had no symptoms of psychologic distress at any point in the study.[235] Similarly, after reviewing how their astronauts performed during missions on the ISS, all crewmembers participating in the study displayed unusually high levels of self-awareness and were generally positive about their time on the ISS, leading NASA to conclude that their training programs regarding interpersonal relationships, teamwork, and psychologic support were effective.[236]

DECOMPRESSION AND CHANGING OXYGEN CONCENTRATIONS

Foreign space objects pose a constant hazard to any manned space vehicle, as any penetrating impact could cause sudden depressurization of the internal cabin environment. NASA estimates that there are now more than 21,000 orbital debris objects (usually human made objects with no further usable purpose or the remains of such objects) in the Earth's atmosphere, and approximately 200 kg of meteorite material (rocky material passing through the Earth's atmosphere while orbiting the sun) is likely to be within 2000 km of the Earth surface at any particular time.[211] Sudden loss of the crew's artificial environment can cause acute hypoxia, decompression sickness (DCS), and ultimately death if the problem is not rapidly resolved or contained. According to the Federal Aviation Administration, the time of useful consciousness (i.e., the amount of time a person can effectively or adequately perform flight duties with an insufficient supply of oxygen) after rapid decompression at 50,000 feet is just 5 seconds.[237]

DCS (commonly known as "the bends") arises when gases usually dissolved are forced out of solution by sudden pressure changes to form generalized bubbles (a process called *ebullism*, body fluids boiling as a result of ambient pressure being less than the saturated vapor pressure of water). Soviet Cosmonaut Alexei Leonov reportedly gave himself DCS in 1965 as he finished making the world's first spacewalk—he needed to reduce the size of his malfunctioning spacesuit in order to fit back through the airlock door into his space craft![238] Space suit design has since improved massively but the dangers associated with performing extravehicular activities (EVAs) remain significant.

American and Russian spacesuits maintain an internal environment of 100% oxygen at either 30 or 40 kPa, respectively. It is a major engineering challenge to build flexible suits durable enough to withhold higher pressures against the vacuum of space.[239] Astronauts undergo pre-EVA procedures before leaving the main spacecraft to minimize the risk of developing DCS during a particular EVA, but despite being relatively time-consuming in spaceflight terms, these pre-EVA activities represent extremely rapid decompression times. Atmospheric pressures between 30 and 40 kPa are equivalent to standing on the summit of Mount Everest at 8848 m. While most climbers would typically take around 60 to 70 days to reach the summit of Mount Everest,[240] astronauts are decompressed to these values within minutes to hours, thus making supplemental oxygen essential to prevent any of the altitude illnesses described earlier in this chapter. However, oxygen represents a major fire hazard to any spacecraft and no manned space programs currently use spacecraft with elevated oxygen levels for this reason. Therefore, some form of decompression procedure currently remains essential prior to any EVA.[239] Although this may not be much of a concern to routine commercial passenger travel into space (passengers will not need to routinely exit their spacecraft), how best to manage these conflicting issues on longer missions to the moon or Mars remains unclear.

MICROGRAVITY

The human body has carefully evolved over millions of years to perform optimally in an environment with gravity. In fact, the effects of gravity on our environment are so ubiquitous that it is challenging to contemplate just how significant a role gravity plays on human health and performance. Without gravity, just attempting to function and interact appropriately with our surrounding environment becomes immensely difficult, and simple phenomena that we take for granted on earth no longer occur. Without gravity, there is also no convection, making temperature control difficult. As an example, burning flames are spherical and blue rather than yellow and pointy; there is no downward soot deposition or upward heat transfer and the flame burns as soon as it reaches any oxygen and in all directions. Without gravity, there is no effect of buoyancy—bubbles do not rise to the surface but remain suspended in fluids (Fig. 74.3). In other words, to remove any bubbles from fluid in a syringe requires the application of an external accelerative force. Weightlessness has an impact on almost every organ system in the body, posing a number of both acute and chronic health risks to astronauts. A future mission to Mars raises further challenges as astronauts will need to be able transition from weightlessness to functioning in a gravitational environment again within minutes after landing.[211]

Cardiovascular Physiology During Space Flight

The cardiovascular system is particularly susceptible to the effects of microgravity. Shortly after takeoff, an acute "fluid shift" quickly occurs as fluid usually held in the venous (high capacitance) side of the circulation starts to rapidly redistribute throughout other tissue beds (Fig. 74.4). This effect is most marked in the upper body with up to 2 L of the blood normally pooled in the venous system in the legs by gravity is released upward into the central circulatory system within minutes of launching.[241] Astronauts quickly develop facial edema and a so-called "chicken leg" syndrome as a result of this shift.[210]

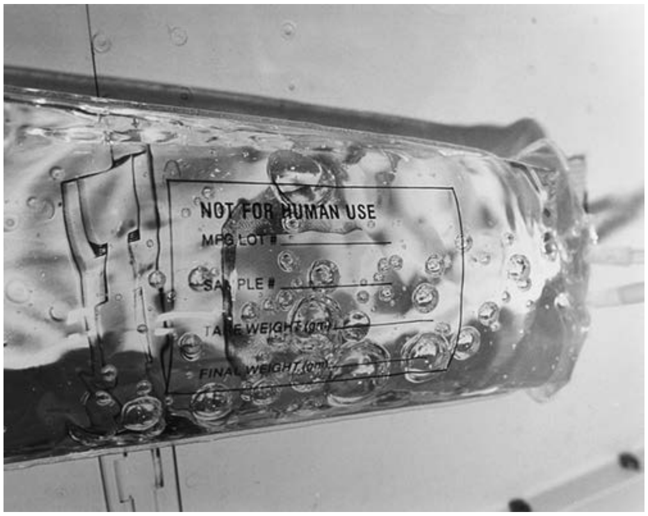

Fig. 74.3 A 1-L bag of 0.9% saline during an orbital flight with air bubbles clearly visible throughout the bag because of the lack of gravitational forces. (From Norfleet WT. Anesthetic concerns of spaceflight. *Anesthesiology*. 2000;92(5):1219–1219.)

Different studies suggest that cardiac output increases between 18% and 30% acutely in response to weightlessness and that this increase persists for at least 8 days.[242-244] This increase is driven predominantly by increases in stroke volume as overall HR appears to remain relatively unchanged.[243-245] Systemic vascular resistance (SVR) also decreases by 14% to 35%, leaving systolic BP relatively unchanged,[244,245] although some studies suggest that resting diastolic and mean arterial pressures might both decrease slightly in response to microgravity but still increase as normal in response to exercise.[243,245] These decreases may turn out to be even more pronounced, however, on longer-duration space missions.[245] Paradoxically, central venous pressure (CVP) acutely decreases after takeoff, possibly as a result of increased atrial distension.[246,247] One study of space shuttle astronauts suggested that baroreflex sensitivity at rest might actually increase briefly initially before returning to baseline levels a few days later,[248] but the baroreflex response seems to be chronically reduced after longer (e.g., 9 months) duration missions.[249]

As time in space increases, adaptation to microgravity slowly decreases SV (and cardiac output) again and allows ejection fraction to increase.[250,251] This is presumed to be driven by anatomical changes to cardiac tissue, as left ventricular mass and mean sphericity index may decrease by 8.0% and 9.6%, respectively, together with a drop in total body fluid.[252,253]

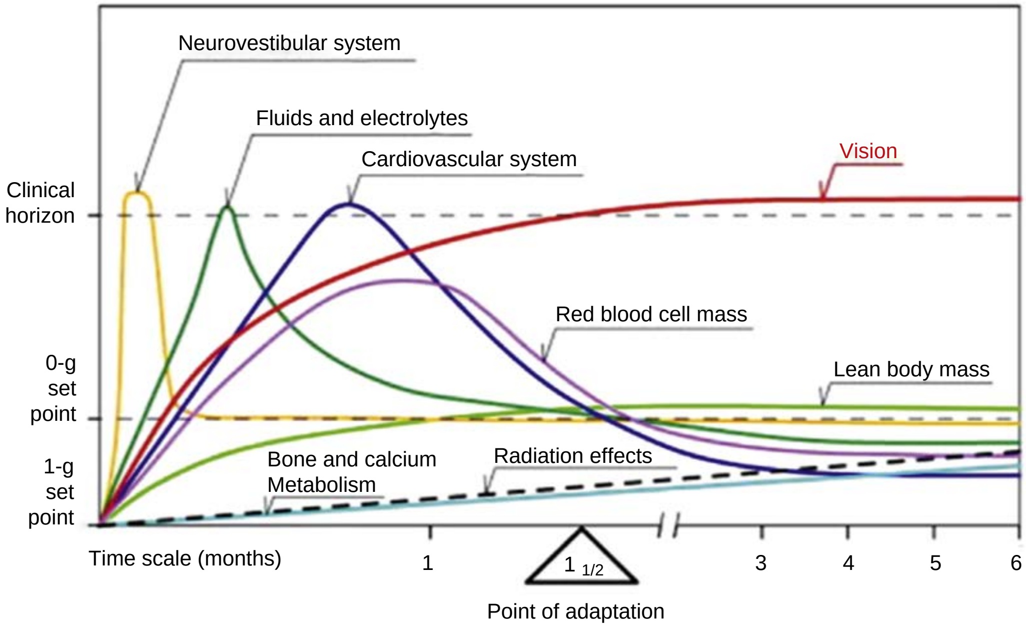

Fig. 74.4 **The time course of physiologic adaptation and acclimatization to microgravity.** (From Komorowski M, Fleming S, Kirkpatrick AW. Fundamentals of anesthesiology for spaceflight. *J Cardiothorac Vasc Anesth*. 2016;30(3):781–790.)

Plasma volume decreases of up to 15% have been reported in both bedrest and spaceflight studies,[254-256] accompanied by similar decreases in total red cell mass.[254,257] Whereas plasma volume decreases within 24 hours, red cell changes take a week to become apparent, suggesting different mechanisms behind each change, but the exact cause of the decrease in red blood cells (RBCs) remains unclear.[210,257] Elevated ferritin levels have been measured after space shuttle missions, but decreased reticulocyte counts suggest this process is because of reduced RBC production and not increased destruction/consumption.[257] But this could also be a result of changes in tissue oxygen levels, particularly in the kidney, as a result of fluid shifting from the lower limbs toward the central (and renal) tissue beds.[210]

Although these fluid changes reverse within 2 to 3 weeks after returning to Earth, initially hypovolemia and orthostatic intolerance still cause astronauts significant problems when they arrive back on Earth. Current protocols require astronauts to “fluid load” with salt water approximately 1 hour before landing, which significantly reduces these risks.[258]

Microgravity itself does not appear to affect cardiac electrophysiology directly. However, a large number of arrhythmias have been reported during spaceflight and particularly during EVAs, possibly due to the many fluid shifts described above and the changes in catecholamine levels and adrenergic receptor sensitivity.[210,259,260] Every one of the nine Skylab astronauts suffered some form of rhythm disturbance during their mission, NASA recorded multiple arrhythmias during its many space shuttle missions, and in 1987 one of the crewmembers on board the Russian MIR space station recorded a 14-beat run of ventricular tachycardia (VT).[210,211]

Pulmonary Physiology During Space Flight

Human lungs are normally exquisitely sensitive to gravity, which induces relevant gradients to both ventilation distribution and pulmonary blood flow. Consequently, it is not surprising that pulmonary function alters during spaceflight away from the Earth’s normal gravity environment.[242,261] However, adaptive changes remain remarkably short lived and, unusually, no pulmonary recovery or rehabilitation is commonly necessary when astronauts do return to Earth.[262] Whether this would also remain true after future space missions with durations longer than 6 months currently remains unproven.

More specifically, respiratory rate increases by around 9% in microgravity but tidal volume decreases by up to 15%, meaning that minute alveolar ventilation remains essentially unchanged overall.[210,242,263] Other respiratory measurements don’t alter significantly either with space flight. Measurements suggest that although vital capacity, forced vital capacity, and FEV1 may all decrease marginally (by around 2%-5%) within 24 hours of entering microgravity (Fig. 74.5), by the fourth day of spaceflight all have returned to pre-flight values.[211,264] Residual volume decreases by around 18% in space (approximately 320 mL) and consequently functional residual capacity also reduces by around 15% (approximately 500 mL) in microgravity, possibly because of cranial movement of the diaphragm, more uniform alveolar expansion, and increased intrathoracic blood flow.[263] However, although ventilation and blood flow are more uniform throughout the lung in microgravity, a small and clinically insignificant degree of ventilation perfusion mismatch still remains even in space.[211,265]

On average, ISS astronauts’ exercise capacity (as measured by $\dot{V}O_2$ peak) decreases in the initial stages of their space flight (by 17%) but then continues to gradually normalize again throughout the remainder of their mission. Although some astronauts were able to reach their pre-flight value, others were not, suggesting considerable interindividual variability in exercise-responses to spaceflight.[266] The fact that aerobic capacity increasingly recovers as flight durations lengthen suggests this is a successful response to exercise countermeasures employed during and throughout each ISS mission.[267] All astronauts undergo an individually tailored daily exercise regime whilst in space to counter any aerobic deconditioning, but this countermeasure program has continued to evolve over the years as both knowledge and the equipment available for use on the ISS has changed and improved. While the relative contribution of both treadmill running and cycle ergometry has steadily decreased over the last 10 years of ISS missions to just 30 minutes of each on average per day, the number of resistance exercises in these programs has gradually increased to around an hour a day.[268] HR only increases marginally on return to Earth after long duration space flights, suggesting that these programs can successfully maintain astronauts’ cardiovascular fitness to enable them to meet the demands of daily mission activities.[269] Another one of the main aims of this rigorous exercise regime is to counter the significant muscle atrophy and bone demineralization that occurs under conditions of microgravity (Fig. 74.6).

Musculoskeletal Physiology During Space Flight

Marked bone demineralization starts immediately after entering space and leaving Earth’s gravity. Urinary and

Fig. 74.6 European Space Agency (ESA) Astronaut Samantha Cristoforetti exercising on the International Space Station. (Image courtesy ESA.) (From European Space Agency. http://m.esa.int/spaceinimages/Images/2015/09/Samantha_running_in_space. Published 2015.)

fecal calcium excretion increase by 60% to 70% in the first day of space flight, and continues throughout the mission's duration along with notable increases in urinary levels of bone resorption markers and decreases in blood levels of both parathyroid hormone and 1,25 dihydroxy vitamin D.[241] On Earth, the average loss of bone density as a result of aging is approximately 1% per year, whereas in space, bone density decreases an average 1% per month and the rate can be double in the pelvic bones.[210,211] Exercise countermeasure programs (particularly resistive exercise elements) can mitigate these effects and are improving each year, but they are not able to curtail these effects and the risks of fragility fractures and renal stones during space flight remain high among astronauts (and are major concerns for future Mars mission planners), as do long-term health risks such as osteoporosis.[210,270,271]

Similarly, studies of astronauts and cosmonauts on both U.S. space shuttle missions and the Russian Mir missions of 16 and 28 weeks' duration demonstrated significant decreases (5%-17%) in muscle volume in all muscle groups except the neck.[272] Muscle groups normally required to maintain an upright posture are usually most affected (i.e., antigravity muscles). For example, muscle volume loss in ISS crewmembers was greatest in the calves (10%-16% reduction) and in the thighs (4%-7% reduction), whereas no change was seen in upper limb muscle volume.[273] Vastus lateralis muscle biopsies taken from 8 astronauts on early space shuttle missions up to 11 days long confirmed that relative losses were greatest in type IIB and then type IIA (fast twitch) muscle fibers, with type I (slow twitch) fibers changing the least.[274] Functional muscle impairment also occurs alongside these structural muscle changes in response to microgravity, with increased muscle fatiguability and decreased muscle-fiber strength also seen most extensively in antigravity muscle groups.[273] It is notable that decreases in muscle function during space flight are out of proportion with the loss of muscle structure alone. Other factors, including neuronal muscle control, may also contribute.[275] A study by Antonutto found that maximal explosive power decreased between 45% and 65% in spaceflights of 1 to 3 months' duration, while muscle mass only decreased by 9% to 13% during the same period.[276] Electromyographic cycle period and burst durations were decreased in Rhesus monkeys after simulated spaceflight,[277] and significant amounts of dendritic remodeling have been noted in rats on board the ISS.[278]

Central Nervous System and Psychological Challenges During Space Flight

Astronauts commonly experience neurologic changes soon after they arrive in space and also rapidly after their return to Earth, with many of these deficits persisting for long periods after their return. For example, most crewmembers have had some form of locomotion dysfunction after transiting into or out of microgravity, such as ataxia or postural instability. Postural instability may be explained by a number of factors: differential muscle wasting affects postural tone; unloading of the spine means astronauts can gain 2 to 3 inches in height within 10 days of arriving in space, causing stretching of spinal nerve roots and altering the usual length-tension relationship of different muscle compartments (including antigravity muscles most affected by wasting in microgravity); and changes to vestibular feedback loops (the cerebellum and the vestibular system are usually finely tuned to the Earth's gravity) can also significantly impair normal postural reflexes.[275]

The vestibular system, composed of the semicircular canals and otoliths that sense distant angular and linear forces, respectively, is constantly updating the brain about the head's three-dimensional orientation and movement. However, this system has evolved and developed over thousands of years to be finely tuned to the Earth's gravitational field and not a microgravity environment, making vestibular problems in space extremely common.[275] Between 60% and 80% of all astronauts will experience "space motion sickness" within 48 hours of arriving in space, a condition characterized by symptoms of pallor, anorexia, nausea, sometimes vomiting, increased body warmth, and cold sweating.[279] It is usually a short-lived phenomenon, with most cases either resolving spontaneously or with minimal pharmacologic treatment within 48 to 72 hours, but occasionally symptoms can persist longer. Rarely has this condition led to crew members being incapacitated for an entire space shuttle mission.[241] It poses a real challenge to astronauts contemplating missions of long duration to either the moon or to Mars, where they may need to function normally in a new gravitational environment very shortly after landing in order to survive.

Terrestrial motion sickness commonly results from discrepancies between visual and vestibular perceptions of motion. Similarly, lack of any vestibular sense of "up or down" in the unique, weightless environment of space may also contribute to the development of space motion sickness.[241] Microgravity affects other sensory systems too. American and Russian astronauts have reported that foods taste and smell different in space with requests for spices to enhance many foods tasting more bland, as well as having less of a desire for coffee and sweets.[211] Similarly, astronauts are constantly affected by noise during spaceflight with life support systems operating constantly. While ear plugs can block out the noise (typically at levels of 70 to 100 dBA running constantly in very close proximity, 24 hours a day), they do not attenuate the vibrations caused by these machines. However, the headward fluid shifts associated with microgravity may also impair middle ear function and may attenuate the sense of vibration to some degree.[211] Microgravity also impairs proprioceptive sense of limb position and modifies tactile sensitivity with a significant degree of interindividual variability.[280]

The visual system is particularly affected by spaceflight. Anatomical and functional changes, including disc edema, cotton wool spots, choroidal folds, nerve fiber layer thickening, globe flattening, and consequent hyperopic shifts in vision have all been reported in seven astronauts examined after returning from long-duration spaceflights on the ISS.[281] In one of these astronauts, who had initially only experienced relatively mild changes after his 6-month flight (unilateral choroidal folds and a single cotton wool spot in the right eye), these changes continued to progress during a second 6-month mission and he developed disc edema and more widespread choroidal folds in the same eye.[282] Soon after returning from this second mission, globe flattening and moderate increases in optic nerve sheath diameters were noted bilaterally. Twenty-one months later, widespread choroidal folds remained in the right eye and spontaneous venous pulsations were also absent.[283] Choroidal folds in astronauts were thought to be caused by increased ICP during spaceflight (possibly secondary to higher rates of resistive exercise, higher atmospheric levels of CO_2 on board the spacecraft, or the cephalad fluid shifts associated with spaceflight), which are transmitted to the eye through increased levels of CSF transiting along the optic nerve sheath and putting more posterior pressure on both globes. In fact, this is "visual impairment intracranial pressure syndrome" as seen in spaceflight and it has similarities to some effects experienced by people visiting high-altitude regions.[284] However, the long-term asymmetry of these findings in this particular subject suggests that ICPs may not be elevated over prolonged periods in space. Instead, visual impairment during spaceflight may be caused by localized changes to CSF flow within the intraorbital portion of the subarachnoid space—in effect causing an optic nerve sheath "compartment syndrome."[285,286]

Unsurprisingly, the effects of these changes on vision during spaceflight are widespread, and particularly during longer duration missions. Almost 30% of astronauts reported deteriorations in both near and distant visual acuity during short spaceflight missions, with this number increasing to 60% on long-duration missions.[281] Older astronauts are more likely to notice changes as lens accommodation declines with age, and astronauts over the age of 40 are now routinely prescribed "Space Anticipation Glasses" to compensate for their new farsightedness in space. Anecdotal changes in visual fields and changes in intraocular pressure were also reported during the early years of the American space program and substantial amounts of evidence now show that transitioning to or from microgravity also impairs ocular movements and reflexes too.[211]

Fig. 74.7 A small winter-over crew at the European Space Agency's (ESA) remote Concordia station in Antarctica. This crew experienced complete isolation, 24-hour darkness, and extremely cold temperatures (down to −80°C) for many months of the year. (Image courtesy ESA.) (European Space Agency. http://m.esa.int/spaceinimages/Images/2016/07/Concordia_crew_2014-2015. Published 2016.)

In addition to coping with changes to their perception, astronauts also experience numerous psychologic challenges before, during, and after their mission. Astronaut selection is extremely competitive and the intensive international training schedule for crewmembers preparing for launch puts intense stresses on all members of the family unit even before the astronaut leaves Earth. Long periods of isolation have been shown to increase levels of stress as measured by activation of the hypothalamic-pituitary-adrenal axis (resulting in increased levels of cortisol production) and a degree of sleep impairment.[287] The increased levels of insomnia astronauts experience is likely multifactorial and not simply explained by isolation alone. For example, low-earth orbit is associated with circadian desynchrony, increased levels of noise, hypoxia, hypercarbia, and extremes of temperatures. However, identifying how best to manage the psychologic stress caused by long-term isolation is critical to the success of any future long-term space missions. International space agencies now run a number of ground-based spaceflight research analog programs specifically to research this (and other) challenges to long-duration spaceflight. For example, the European Space Agency's ground-based research analog program is based at the Concordia station situated high on the Antarctic plateau, which is completely inaccessible for half of the year, completely isolating the dozen crewmembers who "winter-over" there annually (Fig. 74.7). Reports from the Mars 500 project, the first high-fidelity simulated mission to Mars isolating a multinational crew of 6 in a 550 m^3 chamber for 520 days, recently suggested that appropriate selection of crewmembers is key. Substantial interindividual differences were seen in behavioral responses: two crewmembers with the highest ratings of stress and exhaustion accounted for more than 85% of all of the perceived conflicts.[235]

The Effect of Spaceflight on Other Physiologic Systems (Including the Immune and Gastric Systems)

Infectious diseases have been a major concern since the earliest days of space travel. Astronauts were at increased risk of catching infectious disease in the 1960s and 1970s. During that time, approximately 50% of all Apollo astronauts reported suffering from bacterial or viral infections either during or soon after spaceflight.[241] Concerns about how microgravity affects the immune system's responsiveness, and the likelihood of crewmembers becoming increasingly immunocompromised during spaceflight, will continue to grow as we look toward longer-duration missions in the future.[288]

Studies have shown that even short-duration spaceflights impair immune responsiveness with significant increases in inflammatory cytokine production (e.g., IL-4, IL-10, IL-12, and tumor necrosis factor-α [TNFα]) during space shuttle missions, and reduced virus-specific T-cell functionality during spaceflight and soon after landing.[289] The reductions in T-cell function persisted in astronauts participating in ISS missions lasting up to 6 months in duration. Crewmembers on longer missions were more likely to show chronic and persistent reductions in interleukins and TNFα.[290] Impairments in cell-mediated immunity and associated reductions in delayed-type hypersensitivity responses have also been observed in crewmembers on board the Russian Space Station Mir.[291] Reactivation of latent virus activity is also seen in otherwise healthy astronauts; increased shedding of varicella-zoster virus, cytomegalovirus, and Epstein-Barr virus DNA have all been reported during spaceflight.[292-294] Interestingly, an episode of thoracic zoster, typically only seen in either elderly or immunosuppressed patients (e.g., following organ transplant/acquired immune deficiency syndrome), has been observed in an otherwise fit and healthy 47-year-old astronaut 2 days before launch, suggesting the chronic stress of astronauts' rigorous training program may affect their immune responsiveness even before they leave the Earth's atmosphere.[293] Spaceflight may also increase the virulence of infective organisms in animal models, which could compound the problems of immunosuppression developing in crewmembers during longer missions.[295] Ground-based analog research programs (e.g., the Mars 500 project) have suggested that the long-term confinement of space travel could reduce overall microbial diversity and lead to increased selection of opportunistically pathogenic microorganisms.[296] Microbiome changes were also observed during the Mars 500 study, although interestingly even prolonged periods of confinement were not able to compromise individual specificity of different microbiotic compositions.[297] Similarly, changes to the balance of gut bacterial compositions have been seen in astronauts in space but initial findings suggest that overall gut microbial diversity does not alter,[298] although the gastrointestinal system does undergo a number of other changes during spaceflight.

Assessment of nutritional status among astronauts shows that Mir crewmembers undergoing a 4-month mission could lose more than 10% of their pre-flight body mass, and often only manage to eat between 40% and 50% of their predicted energy requirements.[299] ISS crewmembers also lost weight during long missions (128-195 days in duration) and only consumed a mean of 80% of their recommended energy intake. In this study, hematocrit, serum iron, and transferrin levels all decreased, whereas ferritin levels increased even though other acute phase proteins remained unaltered.[300] Serum ferritin levels appear to increase early in spaceflight but transferrin levels do not reduce until later on in the mission, suggesting iron is being mobilized and moved into storage tissues.[301] Overall, gastric motility is significantly reduced for the first 72 hours of spaceflight, nausea and vomiting tends to increase in astronauts during the same time period, and increased levels of gastric acidity have also been reported.[210,214]

Potential Medical Scenarios During Manned Space Missions

Despite all the physiologic challenges with spaceflight, mortality rates among astronauts have continued to steadily decline over the last 30 years,[302] possibly due to improved screening, selection, and training of future astronauts. However, this could also represent a steady improvement in our understanding and ability to manage physiologic problems associated with spaceflight. Astronauts' risk of dying from cardiovascular disease and cancer are now greatly reduced, yet they continue to be at increased risk of accidental death when compared to the general population.[302] However, Apollo astronauts who flew to the moon (the only humans to have ever completely left the Earth's atmosphere) experienced four to five times higher cardiovascular mortality rates than all other astronauts, suggesting that longer distance missions (with increasing radiation exposures) will pose even greater health risks to future crewmembers flying to the moon or Mars.[303]

Throughout 70 years of manned spaceflight, most fatalities and near misses have occurred during takeoff or re-entry/landing. Although increased rates of "in-flight" emergencies must be expected on longer deep space missions, astronauts are relatively young, highly screened individuals with very few medical comorbidities. When "space tourism" becomes more commonplace and members of the paying general public start entering low-earth orbits, then the need to be able to manage chronic conditions in space will become more of a concern. Until that time though, medical emergencies in space are likely to either be acute medical events (e.g., sudden onset cardiac arrhythmia or traumatic injuries following a burn or explosion) or other conditions related to specific physiologic changes caused by spaceflight (e.g., space motion sickness/vision impairment intracranial pressure syndrome or radiation exposure).[210,214] Astronauts may experience different health care needs for many years after spaceflight too. For example, astronauts may have long-term or permanent visual changes as discussed earlier and astronauts are more likely to develop atrial fibrillation at younger ages than the general population, possibly because of transient changes in left atrial structure that can occur after as little as 6 months in space.[304]

Because of the extreme distances involved in deep space missions, any crew will have to be totally autonomous in a medical emergency. Although “telemedicine consultations” with an appropriate physician back on Earth might be possible for minor ailments, the transmission delays would render this useless if an acute event happened on the far side of the moon. Interestingly, when asked about future Mars missions, most American astronauts said they expected health problems to occur during any such mission and would want their crew to include an appropriately trained physician (with 4-6 years of experience including management of acute medicine, emergencies, and aerospace physiology).[305] Anesthesiologists and critical care physicians should be well placed to manage space medical issues, both because of their familiarity with acute emergencies of this nature and their excellent understanding of human physiology and pharmacology. The Exploration Medical Capability (ExMC) arm of NASA’s Human Research Program has developed a list of at least 17 conditions that may potentially require general anesthesia or critical care techniques to successfully treat during an exploratory deep space mission. These include traumatic head injuries that require burr hole excision; cellulitis/abscess requiring incision and draining; or reducing a shoulder or elbow dislocation (Table 74.2).[306] The European Space Agency estimates that there is approximately a 2.5% chance that a crew traveling to Mars may need to use general anesthesia to manage a medical emergency en route—a highly challenging (and potentially mission limiting) situation for a completely autonomous team to manage without an anesthetically trained physician on board.[306]

Thoughts and Considerations for Anesthetic Provision in Space

GENERAL PRINCIPLES

It is currently possible to evacuate a crewmember from the ISS and return them to Earth for treatment within 24 hours; however, this will not be possible on an exploratory mission deeper into space. No human has yet required general anesthesia to be performed in space and it is not ethical or appropriate to test protocols on healthy crewmembers in space, making it difficult to plan appropriate contingencies for future longer-duration missions.[307] However, Earth-based models and accounts about the provision of anesthesia in remote and isolated environments do exist, such as at high altitude.[185] Lessons can be extrapolated from these to plan for how best to deal with a medical situation that requires anesthesia during long-duration spaceflight. Common themes include a lack of space and medical equipment; limited skillsets and lack of support; little monitoring; need for flexibility and the ability to improvise appropriate solutions quickly; and increased levels of stress with potential negative impacts on performance.[307] However, with adequate training and planning to ensure appropriate redundancy in skills and equipment, providing basic but safe anesthetic care should theoretically be possible in a deep space environment in an emergency.[307]

TABLE 74.2 A List of Possible Medical and Surgical Conditions That Could Potentially Require Anesthetic Intervention During Deep-space Flight

Condition	Example of Surgical Anesthesia	Suggested Anesthesia
Abdominal injury	Splenectomy, bowel excision	GA ETI
Back injury, lumbar spine fracture, neck injury	Fracture reduction, halo traction application, osteosynthesis	GA ETI
Burns	Dressing, fasciotomy	GA SV
Cellulitis	Incision and drainage	GA SV
Chest injury/pneumothorax	Thoracotomy for hemostasis	GA ETI
Compartment syndrome	Decompressive laparotomy	GA ETI
Elbow dislocation	Reduction	GA SV
Gastrointestinal bleeding	Hemostasis, ulcer suture, bowel excision	GA ETI
Head injury	Burr hole decompression	GA ETI
Hemorrhoids	Excision	GA SV
Hip/lower extremity fracture	Reduction, osteosynthesis, external fixation	GA SV
Intraabdominal infection (diverticulitis, appendicitis, other)	Bowel excision, appendectomy	GA ETI
Nephrolithiasis	Percutaneous nephrostomy, cystoscopy	GA SV
Shoulder dislocation	Reduction	GA SV
Skin laceration	Suture, dressing	GA SV
Upper extremity fracture	Reduction, osteosynthesis	GA SV

GA ETI, General anesthesia with endotracheal intubation; *GA SV*, general anesthesia with spontaneous ventilation.

From Komorowski M, Watkins SD, Lebuffe G, Clark JB. Potential anesthesia protocols for space exploration missions. *Aviat Space Environ Med*. 2013;84(3):226–233.

PREOPERATIVE PERIOD

All astronauts undergo extensive selection and screening prior to leaving earth (Fig. 74.8). Most are extremely fit and healthy individuals who would initially appear to benefit little from most preoperative interventions. However, one important consideration might be preventative surgery prelaunch to prevent on-board emergencies later. It is not known whether the physiologic changes associated with spaceflight will alter the relative risks of developing acute appendicitis or cholecystitis in crewmembers undertaking deep space missions. Increased rates of appendicitis and atypical presentations are seen in Antarctica, possibly because of altered immunological responses, so a similar increase could be possible in space as well.[308] Similarly, whether space travel might affect rates of gallstone formation (e.g., through altered lipid/cholesterol metabolism and fluid shifts) also remains unknown, although interestingly

Fig. 74.8 European Space Agency (ESA) Astronaut Timothy Peake undergoes practical lessons in medical procedures and techniques at the European Astronaut Centre (EAC) before his mission on the International Space Station. (Image courtesy ESA.) (From Baumbach D. European Space Agency. http://www.esa.int/spaceinimages/Images/2010/02/Timothy_Peake_during_training_at_EAC_January_2010. Published 2010.)

it is becoming more commonplace for patients recognized as being at higher risk of gallstone disease progression (e.g., obese patients undergoing bariatric surgery) to be offered prophylactic cholecystectomy surgery. Whether or not the minimal risks of prophylactic surgery on Earth would outweigh the risks of an emergency occurring during a 900-day mission to Mars remains unclear.[308]

General Anesthesia in Space

In all probability, the skillset or experience of any crewmember performing anesthesia in space is likely to be limited. Consequently, it seems sensible to encourage simple, protocol-driven techniques that use minimal drugs and equipment for performing general anesthesia in space. Ketamine has been advocated as the induction agent of choice because of its ability to induce dissociative states of anesthesia and provide both analgesia, sedation, and hypnosis via multiple routes (intramuscularly, intravenously, orally, intranasally, intrarectally) while maintaining relative hemodynamic stability even in the relatively hypovolemic states that are likely to be encountered in space. Importantly, ketamine can also be stored in either crystal or powder forms for long periods and remains stable over a wide range of different temperatures. In addition, the relative contraindications to ketamine use (e.g., ischemic heart disease, valvular pathologies, epilepsy, severe arterial hypertension, or pulmonary hypertension) are not likely to be present in highly-selected astronauts.[306] Ketamine has been used to manage emergency situations in remote and resource-poor regions and maintains a reasonable safety profile.[185,196,309-311]

Tracheal intubation has been performed successfully in short flying simulations of microgravity environments, but any attempt at intubation in space is likely to be difficult for multiple reasons. All intubation techniques in microgravity will necessitate both the intubator and the patient being firmly secured, plus the patient is likely to have significant facial—and possibly airway—edema. Use of laryngeal mask airways (LMAs), cuffed oropharyngeal airways, and intubating LMAs have all been demonstrated successfully in a simulated microgravity environment using a waterbath.[312] However, none of these devices were universally inserted successfully; plus, gastroesophageal reflux is likely more common in space due to increased gastric acidity/decreased motility as described, which makes aspiration a considerable risk during general anesthesia using any supraglottic airway device.

To maximize chances of intubation success, Komorowski and colleagues advocate the use of neuromuscular blocking agents despite the small but potentially serious anaphylaxis risk, and astronauts could always be tested for a possible allergy before launch.[306] Depolarizing neuromuscular blocking agents should not be used during spaceflight because of the risk of cardiovascular collapse secondary to hyperkalemia. There is a possibility that increased acetylcholine receptor proliferation will occur in muscles that have atrophied under conditions of microgravity.[313] Nondepolarizing muscular blocking agents can be used safely without this risk but there are concerns about the dose; based on findings in similarly immobilized patients and patients with neuromuscular diseases, resistance to these agents is expected and requires increased doses.[314] However, this has never been tested or validated in astronauts in space and, unlike these cohorts, astronauts are continuously undergoing rigorous resistance exercise regimes during spaceflight to minimize muscle disuse. Rocuronium is likely to be the best choice of neuromuscular blocking agent for many reasons: chiefly, it has a rapid onset of action and a rapid sequence induction is likely to be preferred given the increased aspiration risk[306]; and it can now be rapidly reversed using sugammadex if needed (e.g., unexpected failed intubation, which is much more likely in space for all the reasons discussed earlier).[315,316]

Astronauts are likely to be both relatively anemic and hypovolemic, which increases the risk of cardiovascular collapse during any anesthetic induction in space. Available volume resuscitation products are likely to be limited and also need to be prepared and used extremely carefully. All blood products currently have too limited a shelf-life to be carried on all but the shortest space missions, and in microgravity fluids and gases do not separate out based on their different densities (normally on earth, less dense air will always rise to the top of the fluid bag). Consequently, in space a drug vial or fluid bag will contain a fluid more like foam. All intravenous fluid bags will need to be “degassed” before use and likely need to be mechanically pumped in some way as flow will not be aided by gravity.[313]

Strict environmental controls are likely to enforce totally intravenous methods of maintaining anesthesia (total intravenous anesthesia [TIVA]), as scavenging of volatile gases could be challenging (and traditional vaporizers would not work in microgravity). Relatively simple methods for ketamine-only TIVA have already been described elsewhere and would minimize the need for training in and transporting different agents.[306] It would also be essential to use the lowest safe inspired concentration of oxygen, as exhaling large concentrations of oxygen will dangerously increase the onboard fire risk. Other considerations include the need to take care with endotracheal cuff pressures in the microgravity environment.

Regional Anesthesia in Space

Regional anesthetic techniques and approaches could offer many advantages over the many risks associated with performing general anesthesia during spaceflight. In an emergency setting or situation with limited resources, it would be possible to perform almost any limb operation with the knowledge of just three regional blocking techniques. Together, a combined sciatic and femoral nerve block would give complete anesthesia of the leg, and an axillary brachial block would anesthetize the arm below the shoulder.[210]

Large systematic reviews have concluded that using ultrasound-guided techniques to deliver regional anesthesia improves both block safety and success rates.[317] Astronauts have already successfully performed ultrasound examinations on themselves accurately and safely on the ISS,[318] showing that they are capable of learning ultrasound techniques and this technology can be used safely in low earth orbit. However, an ultrasound-guided regional block has not yet been performed in space and similar challenges would have to be expected. As for the intubation, both the operator and the patient need to be secured in some way, and success rates could considerably decrease due to neuromuscular and proprioceptive changes associated with spaceflight. Plus, regional anesthetic approaches would not always be suitable for any condition and still require a considerable amount of specialist training to develop reasonable levels of competency, again potentially decreasing their suitability for use by medically inexperienced crewmembers on board an exploratory deep space mission.

The use of telemedicine technology has also been proposed to aid astronauts in space and could theoretically allow a ground-based operator to remotely perform regional anesthesia on board a distant spacecraft in the future. Remotely operated robotic surgery has already been tested in consideration for use in future space missions; for example, over 30 robotic telesurgical procedures have been performed remotely across Canada using internet links with latencies of approximately 140 ms.[319] However, a radiolink to a deep exploratory spacecraft orbiting Mars could expect to experience delays of nearer to 40 minutes because of the extreme distances involved![313]

Clinical Care in Extreme Environments: High Pressure, Immersion, Drowning, Hypo- and Hyperthermia

RICHARD E. MOON, ANNE D. CHERRY, and ENRICO M. CAMPORESI

KEY POINTS

- Immersion in water causes acute redistribution of blood from the extremities and splanchnic vessels to the heart and pulmonary vessels. This can precipitate pulmonary edema (immersion pulmonary edema [IPE], swimming-induced pulmonary edema [SIPE]) in some individuals, especially during heavy exercise or in the presence of myocardial dysfunction. SIPE usually responds to removal from the water and oxygen therapy.
- Prolonged immersion induces diuresis and plasma volume loss that can predispose to severe postural hypotension after extraction from the water.
- Care of a drowning victim includes resuscitation when necessary, oxygen, and supportive care. All victims of drowning who require any form of resuscitation should be transported to the hospital for evaluation and monitoring, even if they appear to be alert and demonstrate effective cardiorespiratory function at the scene.
- In victims of either hypothermia or hyperthermia optimal temperature measurement should be core (rectal or pre-ingested capsule).
- Extracorporeal life support (ECLS) for both circulatory support and controlled rewarming is usually recommended for core temperature less than 30°C.
- Suspected victims of heat exhaustion or heat stroke should be assessed with rectal temperature measurement. Victims of heat exhaustion (temperature normal or slightly above normal) can usually be treated with minimal external cooling. Heat stroke (core temperature 40°C-47°C) should be treated aggressively, ideally with immersion in ice water until core (rectal) of 39°C or less is reached.
- Hyperbaric oxygen exposure (breathing oxygen at increased ambient pressure, typically 2-3 atmospheres absolute [ATA]) causes an increase in arterial and tissue partial pressure of oxygen (PO_2) and no significant change in arterial pH or partial pressure of carbon dioxide in arterial blood (PCO_2).
- During hyperbaric oxygen therapy cardiac output and pulmonary vascular resistance are decreased; systemic vascular resistance is increased.
- Acute illnesses for which hyperbaric oxygen is indicated include carbon monoxide (CO) poisoning (based on randomized, controlled studies), gas bubble injury (gas embolism and decompression sickness [DCS]), and soft tissue necrotizing infections (the latter two based upon clinical experience and meta-analyses).
- The decision to use hyperbaric oxygen to treat a patient with arterial gas embolism (AGE) or DCS should be based on clinical criteria, including the presence of symptoms, abnormal physical examination, or a history of AGE within a few hours even in the absence of symptoms. Neither neurophysiologic testing nor radiographic imaging are useful except, rarely, to exclude other pathologies.
- The decision to use hyperbaric oxygen to treat a patient with CO poisoning should be based on clinical criteria, including a history of impaired consciousness or other neurologic manifestation, pregnancy, or severe exposure (e.g., peak carboxyhemoglobin [HbCO] more than 25%). The HbCO level correlates poorly with the severity of the illness and is generally useful only to make the diagnosis.
- Oxygen-induced seizures are rare and self-limited. Appropriate management includes discontinuation of inhaled oxygen. Chamber pressure should not be altered during the seizure, as decompression while a seizure is occurring can result in pulmonary barotrauma (pneumothorax or pneumomediastinum) and AGE.
- Recent animal and human data support the notion that pretreatment of patients with hyperbaric oxygen may ameliorate some of the adverse effects of cardiac surgery and invasive cardiac procedures.
- As ambient pressure is altered, anesthetic vaporizers (except for desflurane) deliver a variable concentration but fixed partial pressure of vapor. Therefore, there is no need to adjust vaporizer settings when delivering anesthesia in a hyperbaric chamber or at altitude. Desflurane vaporizers deliver a fixed concentration, requiring upward adjustment at altitude.

Introduction

Anesthesiologists and other intensivists are frequently required to evaluate and treat patients suffering consequences of exposure to high and low temperatures, high ambient pressures, gas embolism, decompression sickness (DCS), and drowning. Administration of oxygen (O_2) at increased ambient pressure (hyperbaric O_2, hyperbaric oxygen treatment [HBOT]) has been used since the early 20th century for selected conditions. It is an effective modality for treatment of gas bubble diseases and several other acute and chronic conditions. This chapter describes the physiology of immersion and its complications, hypo- and hyperthermia, and the use of HBOT for treatment and its indications for acute treatment.

Physiology of Immersion

ACUTE EFFECTS OF IMMERSION

The upright posture of humans results in gravitational effects on the venous blood pool, which tends to be distributed into the lower half of the body. Because water and blood have almost the same density, immersion in water causes immediate redistribution of blood from the legs and splanchnic bed into the heart and pulmonary circulation. This causes a reduction in lung volumes, a rise in central venous and pulmonary vascular pressures,[1,2] and an increase in ventricular and stroke volumes.[3] These effects are accentuated in cold versus warm water due to peripheral vasoconstriction.[4,5]

PROLONGED IMMERSION AND RESCUE

Because of atrial stretch, there is an increase in B-type natriuretic protein (BNP) secretion. In conjunction with the increase in cardiac output this induces a diuresis. Prolonged immersion, such as may occur during loss at sea, can result in severe hypovolemia due to lack of fluid intake and prolonged diuresis. Indeed, some marine accident survivors have died during extraction from the water in the vertical position.[6] It is therefore recommended that victims who have spent significant time in the water be kept in the horizontal position during rescue (Fig. 75.1).

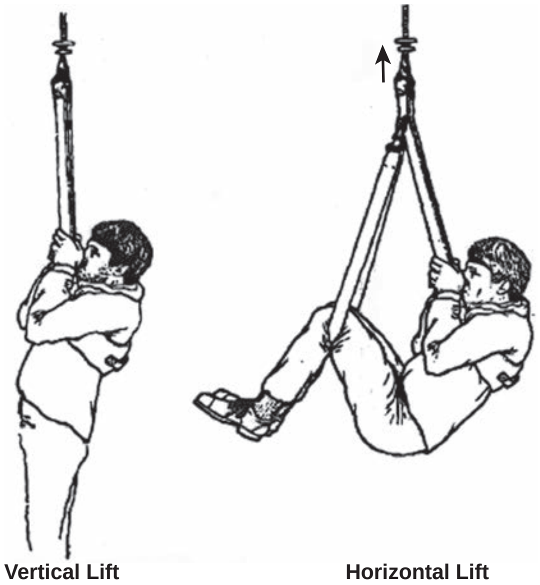

Fig. 75.1 Two methods of extracting a victim from the water. After immersion for 30 minutes in 15°C water, heart rate changes were measured during removal in two different positions. During vertical lift mean heart rate increased by 16% due to reflex response to hypotension versus only a small nonsignificant increase during horizontal lift. Extracting victims in the vertical position has resulted in death, presumably due to hypotension. (From Golden FS, Hervey GR, Tipton MJ. Circum-rescue collapse: collapse, sometimes fatal, associated with rescue of immersion victims. *J R Nav Med Serv*. 1991;77[3]:139–149. [Page 146, Fig. 3] with permission.)

IMMERSION PULMONARY EDEMA

Pulmonary vascular pressures that are elevated due to immersion are increased even further during exercise, particularly in cold water.[5] Drinking water prior to immersion can activate the osmopressor response[7,8] and further augment central translocation of venous blood. Blood centralization then raises pulmonary vascular pressures, which in susceptible individuals can be sufficiently elevated to induce acute pulmonary edema. This condition is referred to as immersion pulmonary edema (IPE) or swimming-induced pulmonary edema (SIPE). Individuals with cardiovascular pathology, such as hypertension, left ventricular hypertrophy, cardiac valve disease, and cardiomyopathy are particularly susceptible because of their preexisting elevation of left atrial pressure.[9] However, healthy individuals can also experience SIPE, particularly during heavy exercise in the water. SIPE has been reported during a long swim in approximately 1.5% of triathletes,[10] 3% to 5% of US Navy special forces trainees,[11] and up to 60% of Israel Defense Force recruits.[12] SIPE tends to recur in some individuals and has been linked to higher than normal pulmonary artery (PA) and PA wedge pressures.[13]

The condition usually resolves within a few hours after removal from the water (which immediately reduces intravascular pressure within the pulmonary vessels) and administration of first aid O_2. Nebulized β_2-adrenergic agents may be helpful to treat bronchospasm and accelerate water reabsorption from alveoli.[14] Although resolution within a few hours is the norm, SIPE-induced death has been reported.[15]

Drowning

DEFINITION

A definition of drowning was proposed and adopted in 2002 by the World Health Organization as follows: *Drowning is the process of experiencing respiratory impairment from submersion/immersion in liquid.*[16] This definition was modified slightly by a consensus of international investigators on guidelines for the uniform reporting of data from drowning studies (Utstein style),[17] which has subsequently been updated.[18] A recent publication has reviewed 14 drowning publications based on this reporting convention.[19]

Evolution of the drowning syndrome in a patient depends on the extent of aspiration of fluid into the airways, leading to hypoxemia and cardiac arrest, which can evolve to progressive and irreversible neurologic damage. Death at any time as a result of drowning is described as *fatal drowning*. When the process of drowning is interrupted, it is referred to as *nonfatal drowning*. Any submersion incident without respiratory impairment should be considered a *water rescue* and not a drowning. Other terms such as "near drowning" or "dry" or "wet drowning" or similar distinctions should not be used, in order to standardize appropriate reporting of outcomes.[20-23]

PREVALENCE

The number of accidental drownings in the world exceeds 500,000 persons per year,[24] causing over 370,000 deaths.[25] Undoubtedly these numbers are underestimates due to additional unaccounted cases such as the thousands of victims each year from floods, tsunamis, and asylum seekers seeking to flee by sea. Approximately 20% of people who die from drowning are children younger than 15 years of age. From 2005 to 2014, there was an average of nearly 3900 fatal unintentional drownings per year in the United States.[26] It is estimated that 4000 children receive emergency department care for nonfatal submersion injuries. At least 50% of drowning victims treated in hospital emergency departments require inpatient care. Nonfatal drowning can lead to severe brain damage and long-term disability.[26]

These statistics show that drowning is a significant public health issue, surpassing the number of annual traffic accident deaths. However, multiple agencies at a national level follow and attempt to regulate traffic, whereas drowning has not elicited appropriate attention.[27]

PATHOPHYSIOLOGY

After submersion in water when a person cannot maintain a clear airway, water is voluntarily expelled from the nose and mouth and breath-holding is initiated. This usually cannot last more than one minute, because involuntarily inspiratory efforts produce swallowing attempts, water inhalation, and cough. Laryngospasm may occur for some time but will cease during progressive brain hypoxia.

Continued water aspiration leads to hypoxia, loss of consciousness, and deterioration of cardiac function. The hypoxic cardiac insult can rapidly progress through tachycardia, followed by bradycardia, pulseless electrical activity (PEA), and finally asystole. Irreversible damage to the heart and the brain usually occurs within a few minutes. In exceptional but rare circumstances, such as drowning in ice water, cardiac and brain cooling can provide extended hypothermic protection and afford possibility of reversible resuscitation after prolonged submersion times,[28] although systematic reviews have failed to find a correlation between water temperature and survival.[29,30] Drowning in cold water may also be accompanied by several unique aspects related to gasp response, autonomic effects, hemodynamic changes, and hypothermia (see later).[31]

Water aspiration induces pulmonary edema with impairment of pulmonary gas exchange, in part due to surfactant dilution and dysfunction.[32] Although conventional wisdom is that fresh and salt water drowning differ due to osmotically driven fluid exchange across the alveolar-capillary membrane with resulting changes in electrolyte concentrations, animal studies and clinical case reports have not supported differences in clinical course. A study of hemodynamics and pulmonary mechanics in anesthetized dogs using tracheal instillation of 20 mL/kg of fluid with various sodium chloride (NaCl) concentrations (sterile water, 0.225%, 0.45%, 0.9%, 2%, and 3% NaCl) and anoxic controls failed to find any differences among the groups.[33] This is supported by recent clinical series, where outcomes of drownings were similar in fresh and salt water.[34]

RESCUE AND RESUSCITATION

Enhanced local surveillance by lifeguards has been shown to be highly effective in early rescue and improved outcomes from drowning: the majority of rescued victims in areas of effective surveillance do not need medical attention and only 6% of all rescued persons require emergency medical admission and very few require cardiopulmonary resuscitation (CPR).[35,36]

Safe rescue techniques comprise reaching the victim with a pole, a rope, or other buoyant life-saving device, avoiding rescuer entanglement with the victim. American Heart Association resuscitation guidelines recommend that rescuers should remove drowning victims from the water by the fastest means available and should begin resuscitation as quickly as possible. Since cardiac arrest is caused by progressive hypoxia, any attempt to institute CPR must include ventilatory maneuvers to attempt to refill the alveoli with air or oxygen. For drowning victims who present in cardiac arrest, a shockable rhythm is predictive of survival, but one series reported that most drowning victims in arrest have asystole or PEA.[37]

Rescuers should provide CPR, particularly rescue breathing, as soon as an unresponsive submersion victim is removed from the water. Mouth-to-mouth ventilation in the water may be helpful when administered by a trained rescuer, but chest compressions are difficult to perform in water and are often ineffective. Maneuvers to relieve foreign-body airway obstruction are not recommended. It is reasonable for the lone healthcare provider to give 5 cycles (about 2 minutes) of CPR before leaving the victim to activate the emergency medical service (EMS) system. Victims with obvious clinical signs of injury, alcohol intoxication, or a history of diving into shallow water are at higher risk of spinal cord injury, and thus stabilization of the cervical and thoracic spine for such individuals may be considered, although spinal cord injury among drowning victims is uncommon. Often the victim has swallowed variable volumes of water and can vomit early during rescue-breathing; in patients with spontaneous circulation, the lateral position is therefore recommended to minimize the risk of aspiration.[38]

The clinical presentation of the drowning victim is variable and stratifying risk based on clinical presentation may be useful for initial triage (Table 75.1).[20] American Heart Association guidelines recommend that all victims of drowning who require any form of resuscitation (including rescue breathing alone) should be transported to the

TABLE 75.1 Drowning Severity Scale Described by Szpilman With Outcomes of 1831 Cases

Grad	Description	Hospitalization (%)	Mortality (%)
1	Normal pulmonary auscultation with coughing. Insufficient aspiration of water to cause alteration in alveolo-capillary gas exchange requiring medical intervention.	2.9	0.0
2	Abnormal pulmonary alveolo-capillary gas exchange; abnormal pulmonary auscultation with rales in some pulmonary fields.	14.8	4.0
3	Significant alveolo-capillary gas exchange alteration as well as a high degree of pulmonary arterial-venous shunt that generally requires early mechanical ventilation and PEEP. Pulmonary auscultation with rales in all pulmonary fields, in addition to presenting frequently with pinkish foam in the mouth and nose. No hypotension.	44.8	11.5
4	Same as Grade 3 with hypotension.	88.9*	19.4
5	Isolated respiratory arrest.	84.0*	33.3
6	Cardiopulmonary arrest.	12.4	43.5

*Hospitalization < 100% in this group due to several patients reported dead before reaching hospital.

PEEP, Positive end-expiratory pressure.

hospital for evaluation and monitoring, even if they appear to be alert and demonstrate effective cardiorespiratory function at the scene.[39]

HOSPITAL CARE

The sequence of resuscitation efforts after emergency department admission includes securing a definitive airway, improving oxygenation, reestablishing circulation, insertion of a gastric tube, and rewarming. Previous medical history should be addressed, since trauma, cardiac arrhythmias, or seizures may have precipitated the near-drowning episode. Toxicology evaluation for alcohol or drug intoxication may be helpful to establish causes of impaired consciousness and treatment.

If the patient is unstable, intensive care unit (ICU) admission may be required for observation and weaning from mechanical ventilation, which can usually be accomplished using traditional algorithms. Bronchodilator support may be useful to treat bronchoconstriction and accelerate water clearance from alveoli,[14] but glucocorticoids have not been shown to be effective.[40]

Bronchoscopy might be required for pulmonary toilet or aspiration of solid materials, and secondary pneumonia can occur.[41] It has been reported that aspiration of swimming pool water rarely results in pneumonia whereas it is more common in salt water aspiration and most common after polluted water aspiration; however other studies have found no relationship between the type of water and development of pneumonia.[41]

In a small number of patients admitted to the ICU, pulmonary function can deteriorate beyond the ability of conventional mechanical ventilation to maintain adequate gas exchange. In such cases, administration of surfactant substitutes and nitric oxide has been tried. Case series of extracorporeal membrane oxygenation (ECMO) have also been published.[40,42] Initiation of such measures is best determined on the basis of individual patient requirements. It has been recommended that ECMO should be considered earlier in the course of therapy (e.g., when arterial pH < 7.2, PCO_2 > 60 mm Hg, SaO_2 < 85%) before progressive respiratory failure leads to cardiovascular collapse.[42]

Circulation and Renal support

Inotropes may be required to maintain blood pressure. Renal insufficiency or failure has been described and documented in drowning cases,[43,44] with proposed causative mechanisms including rhabdomyolysis, systemic inflammatory response associated with multiorgan failure, and hypoxic renal injury,[44] although dialysis is rarely required.[44]

Neuroresuscitation

Neurologic outcome after effective CPR in drowning victims has been shown to be similar to all victims of cardiac arrest from all other causes; however, in the rare cases where hypothermia was established in the rescued drowning subject, survival after prolonged periods of submersion have been demonstrated.[28,31] Reports[45] have documented possible beneficial effects of induced hypothermia after resuscitation. It has been suggested that drowning victims with return of spontaneous circulation (ROSC) who remain comatose should NOT be actively rewarmed above 90° to 93°F/32° to 34°C, and victims with ROSC whose core temperature is 93°F/34°C or higher should be cooled to 90° to 93°F/32° 34°C as soon as possible[46]; however recommendations for optimal management of such patients await further studies.

OUTCOME OF DROWNING

If a person is rescued the outcome will depend on submersion duration, EMS response times, volume of water aspirated and its effects, the skill of the providers, and the availability of support systems.[30,46] Outcomes of 1831 cases of drowning are shown in Table 75.1.[20] In a series of 336 drowning-related cardiac arrests, EMS resuscitation was attempted on 154, of whom 27% survived to hospital arrival and 8% survived to hospital discharge. Only 6% were found in a shockable rhythm.[37]

PREVENTION

Increasing documentation and international interest from institutions supported by coastal and fluvial societies and advocacy groups have demonstrated the value of prevention in drowning.[47] Use of life vests in the water and

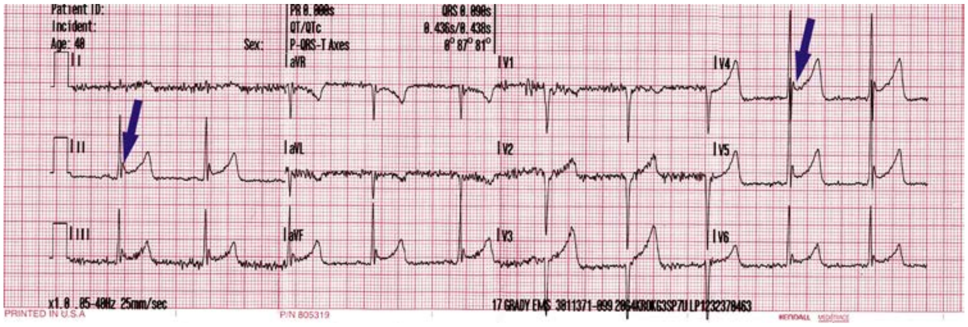

Fig. 75.2 Osborn waves in a hypothermic patient. ECG is from a 40-year-old male found sleeping on the street when ambient temperature was close to 4°C. Rectal temperature on arrival at the hospital was 30.4°C. The 12-lead ECG shows a secondary wave closely following the S-wave *(arrows)*, now referred to as an Osborn wave after the pediatrician/intensivist who first described the pattern as a harbinger of ventricular fibrillation during hypothermia.[53] *ECG,* Electrocardiogram.

instructions teaching swimming and/or floating,[38] as well as Dutch, Brazilian, South African, and Australian lifeguard experiences have shown that 85% of drowning cases can be prevented by public education, supervision, and public preparedness.[31] The recent multiple tragedies of refugees drowning at sea have re-sensitized medical groups to renew efforts to prevent drowning.[27]

Hypothermia

PHYSIOLOGY OF HYPOTHERMIA

Hypothermia is defined by a low core body temperature (generally less than 35°C, with more conservative perioperative thresholds of 36°C[48]). Thresholds for further categorical breakdown into mild, moderate, and severe hypothermia are not consistent within the literature, and vary depending on context (e.g., trauma, immersion/environmental, therapeutic indication). Extremes of age, sepsis, burns, trauma, some endocrine disturbances, intoxication, exertional fatigue, or malnutrition can place patients at higher risk for developing both hypothermia and complications thereof, with a high degree of variability even among healthy individuals.[49,50]

On a molecular and cellular level, decreased temperature decreases the speed of chemical and enzymatic reactions, influences intracellular signaling cascades, and alters cellular structure[51]; the overall metabolic rate is suppressed to varying degrees for different tissues. As such, cold exposure and hypothermia impact each tissue or organ system differently. The microvasculature of the skin and peripheral tissues manifests a rapid vasoconstrictive sympathetic response to either superficial cold exposure or decreased core body temperature. This response reduces skin blood flow and attenuates cutaneous heat flux, while shifting blood volume to the central compartment. The high surface to volume ratio of the extremities can result in profound decreases in peripheral tissue temperatures with maintenance of the core body temperature.

Superficial peripheral cooling impacts muscle and nerve function,[31] which can impair a victim's capability for self-rescue or preservation in the case of accidental hypothermia, and has implications for monitoring in clinical settings (see the section on "Clinical Considerations"). Muscle function declines due to impaired release and diffusion of calcium and acetylcholine, and changes in elastic components. Furthermore, as peripheral cooling progresses and the more superficial muscle fibers become impaired, fatigue occurs more quickly in muscle fibers left to bear the load. Peripheral cooling also impairs nerve conduction velocities and amplitudes, further impacting physical performance. As a final comment on peripheral cooling, accidental hypothermia or improper therapeutic cooling with ice packs or conductive cooling devices can lead to cold injury or frostbite of peripheral tissues (fingers, toes, nose, ears are most susceptible). Treatment is conservative in mild to moderate cases, through protection from mechanical injury, slow rewarming, and consideration of nerve blocks or improving oxygenation when possible. However, tissue salvage in severe injury may also require early therapy with thrombolytics or iloprost.[52]

The cardiovascular system is impacted in a number of ways. Peripheral sympathetic vasoconstriction leads to increased systemic vascular resistance and blood pressure, as well as increased central venous pressure due to redistribution of blood volume to the central compartment. Shivering increases metabolic requirements; in combination with increased sympathetic tone this leads to increased cardiac output, tachycardia, and a propensity for atrial arrhythmias in mild hypothermia. With more severe hypothermia (<32°C), cardiac conduction delays develop, including J waves (positive deflection at the QRS-ST junction) signaling abnormal early ventricular repolarization (Osborn waves, Fig. 75.2),[53] and decreased spontaneous polarization of pacemaker cells, resulting in bradycardia. The likelihood of cardiac arrest increases with cooling below 32°C, with very high risk at 28° to 24°C or below[54]; gentle handling and maintaining horizontal positioning in hypothermic patients can minimize the likelihood of arrhythmia or cardiovascular collapse.

Decreased cerebral metabolism in hypothermia[55] is useful as the basis of neuroprotection for a variety of therapeutic indications and in accidental hypothermia complicated by hypoxia (particularly if cooling occurs before the onset of hypoxia); however, neurologic and respiratory function also decline with increasing severity of hypothermia. Impaired judgment progresses to hallucinations, delirium, and decreased consciousness as body temperature falls; loss of consciousness is common below 28°C. Reflexes, pupillary reactivity, and electroencephalographic (EEG) activity decline and become absent with progressive hypothermia, precluding neurologic assessment. From a respiratory standpoint, neurologic impairment can necessitate intervention for airway protection, and with severe hypothermia respiration can even cease. Although decreased metabolic requirements afford some tolerance to hypoxia and decreased ventilation (tidal volume, respiratory rate, and compliance decrease), sensitivity to hypercapnia is diminished, leading to hypoventilation and acidosis, which can exacerbate electrolyte abnormalities and other physiologic changes.[54]

Renal and hepatic impairment have a variety of implications. Hepatic impairment decreases clearance of lactate and other metabolic byproducts and metabolism of some medications (see the section on "Clinical Considerations"). Renal blood flow is increased in mild hypothermia, due to increased blood volume in the central compartment. Increased renal blood flow in combination with decreased antidiuretic hormone activity results in diuresis. However, as hypothermia progresses, renal blood flow and glomerular filtration rate both decrease, although diuresis may persist due to inhibition of tubular water reabsorption.[54] Additionally, edema that develops in damaged peripheral tissues can exacerbate depletion of circulating blood volume. Respiratory, renal, and endocrine changes result in electrolyte imbalances in both mild and moderate/severe hypothermia. Hypokalemia and hyperglycemia can be present in mild hypothermia, whereas acidosis, increased sodium excretion, and hyperkalemia manifest with progressive cooling.[31] Hyperglycemia results from decreased insulin sensitivity and secretion, requiring intensive insulin therapy and frequent monitoring of blood glucose levels. Distal tubular transport of sodium is impaired, which also affects acid-base regulation.[31] Finally, the threshold for cardiac toxicity from hyperkalemia diminishes with progressive hypothermia.[56] Therapies and medications that increase serum potassium levels (blood transfusion, succinylcholine administration) should be carefully considered in these patients.

Because of increased gas solubility with decreased temperature, arterial partial pressure of oxygen (PaO_2) and arterial partial pressure of carbon dioxide ($PaCO_2$) decrease and pH increases. Samples corrected to patient body temperature will appear to be alkalotic and hypercarbic, whereas samples left uncorrected at 37°C will correspond to normal reference ranges for these values in the absence of physiologic changes. As such, results should be interpreted in the context of whether temperature correction was or was not performed. As discussed in hypothermia, impaired ventilation and a higher ventilatory threshold for hypercapnia result in hypoventilation, which generally tracks with the reduction in metabolic rate. However, since pH increases and increased carbon dioxide (CO_2) solubility decreases $PaCO_2$ with decreasing temperature, cerebral blood flow is generally also decreased in proportion to reduced metabolic rate in hypothermia. Clinically, a strategy that has been investigated in hypothermic cardiac surgical patients is correction for known changes in $PaCO_2$ solubility (known as pH-stat blood gas management, as opposed to alpha-stat management where hypocarbia and alkalosis are permitted), with the theoretical advantage of increasing cerebral blood flow. Some benefit has been shown in pediatric, but not in adult populations, where there is concern for increased cerebral embolic risk.[57]

Hematologic changes observed in hypothermia are secondary to changes in blood volume, microvascular tone, and coagulation factor function. Contraction of the blood volume due to diuresis (possibly combined with dehydration due to environmental exposure or exertion) increases blood viscosity. In combination with increased viscosity, vasomotor abnormalities in the microcirculation lead to sludging, stasis, and hypoperfusion. Impaired circulation prevents tissue oxygenation, but also clearance of metabolic byproducts, which accumulate in peripheral tissues. Leukocyte and platelet counts fall with severe hypothermia and platelet activation and coagulation factor enzymatic function are highly sensitive to pH and temperature.[58] This can result in a coagulopathic state with progressive hypothermia, but may also be partially offset by simultaneous inhibition of anticoagulant factors, depending on relative concentrations.[59]

CLINICAL CONSIDERATIONS

In general, hypothermia may impair drug absorption in the bowel. Both core and peripheral cooling, even to a mild degree (~34°C), can have a clinically significant impact on the recovery from, or twitch response to, neuromuscular blockade. This is explained by both impaired neuromuscular function and pharmacokinetic changes (increased plasma concentration) with decreased temperature.[60] The minimum alveolar concentration (MAC) for volatile anesthetics decreases with hypothermia. With profound cooling (~20°C), anesthesia may no longer be needed to prevent movement,[61] although the precise temperature at which EEG silence is achieved is somewhat lower and demonstrates individual variability.[62] Plasma concentrations of some intravenous anesthetics increase because of reduced compartmental clearance; the clearance of CYP450-metabolized drugs (including propofol and ketamine) is also reduced in proportion to the decrease in body temperature.[54] As a result, reduced infusion rates will achieve similar levels of sedation.[63] In parallel, general anesthetic and some sedative medications have an impact on thermoregulation (both vasoconstriction and shivering thresholds are reduced by up to ~2° to 4°C or more), and can contribute to hypothermia.[63,64]

There are also considerations for monitoring hypothermic patients, the most obvious being the measurement of temperature itself. Even in thermoneutral conditions there is very high variability in skin temperature at different sites, an effect which is attenuated but persistent for common core temperature measurement locations (Fig. 75.3).[65] In hypothermia, changes in blood flow distribution exaggerate these temperature variations among site differences. Similarly, rewarming methods can have dynamic effects on temperatures in different tissue compartments (see Treatment of Hypothermia). Apart from the rational yet clinically variable application, the recommendation is "if one's interest lies with the temperature of a specific body tissue, then measure temperature from that site, or a valid surrogate."[65] The guiding principles for measurement of core body temperature are to measure temperature in a location

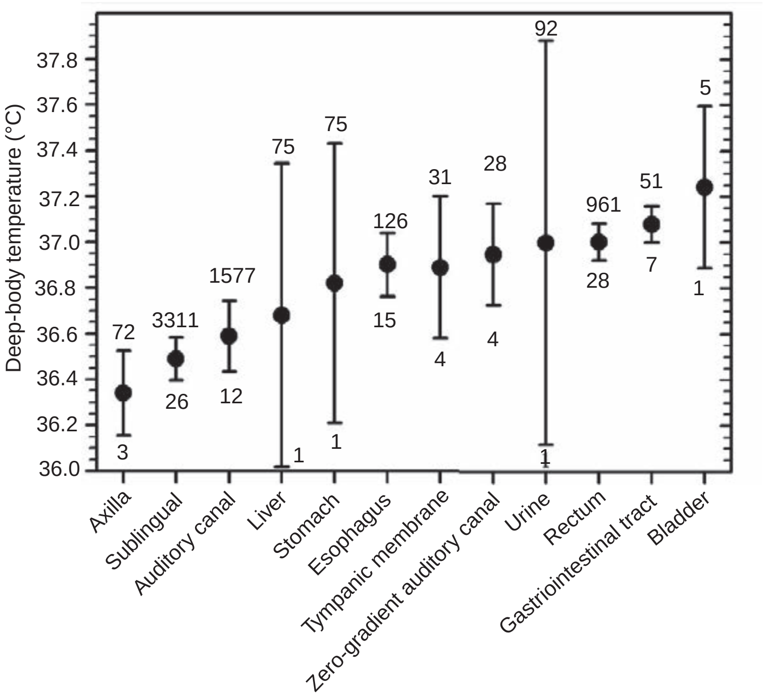

Fig. 75.3 Variations in resting, deep-body temperature in 12 measurement sites from published reports, with means and 95% confidence intervals for each total sample. Numbers above the confidence intervals are the total number of subjects; those below indicate the number of contributing investigations. (From Taylor NA, Tipton MJ, Kenny GP. Considerations for the measurement of core, skin and mean body temperatures. *J Therm Biol.* 2014;46:72–101. [Page 80, Fig. 6] with permission.)

(1) where there is good tissue perfusion, which promotes thermal equilibration with other body sites; (2) that is insulated from the external environment or peripheral tissues, which may be cooled to a greater degree than core tissues; and (3) that is as adjacent as possible to the organ of interest (i.e., the tympanic membrane or nasopharynx for the brain). Blood temperature can be an excellent surrogate for core temperature, with PA blood temperature often cited as a gold standard.[54] However, this invasive method may also suffer some inaccuracy in the setting of acute mixing of fluids administered via central venous catheters or adjacent placement of invasive warming devices. Esophageal temperature is often used to represent blood temperature due to its proximity to the central circulation.

The response time for pulse oximetry is limited or the signal may fail altogether in conditions of local hypoperfusion, as occurs with peripheral vasoconstriction in hypothermia. Although there have been advances in device algorithms, pulse oximetry often does not give a reliable reading from the digits in even mild hypothermia, with relatively preserved performance for ear or forehead sensors.[66] Similarly, concerns for exaggerated or prolonged neuromuscular blockade can be complicated by the fact that local or body cooling decreases nerve stimulation (mechanomyography) twitch tensions, even in the absence of paralytic medications.[60]

There are important differences between accidental hypothermia due to environmental exposure and induced hypothermia in controlled, clinical situations such as therapeutic hypothermia for neuroprotection or during cardiac surgery. The most obvious difference is that the mechanism of cooling may vary—environmental exposure results in cooling across the skin and body surface, through radiation, evaporation, convection, or conduction from cold air, water, or contact surface (with the exception of drowning, where aspiration and swallowing of cold fluid can impart some degree of "internal cooling"). In contrast, in addition to surface cooling, clinical hypothermia may be induced and maintained by more efficient, evenly distributed, and precisely controlled invasive methods, such as intravascular catheters, cold fluid infusion, or cardiopulmonary bypass. Second, clinical support throughout the period of cooling, hypothermia, and rewarming can mitigate some of the major physiologic perturbations that would otherwise limit hypothermia tolerance or resuscitation and allow cooling to temperatures not tolerated outside of the clinical setting. Death is not uncommon in accidental hypothermia with body temperatures of 24° to 28°C, and the lowest documented temperatures from which resuscitation has occurred for accidental hypothermia are ~13°C[31]; on the other hand, recovery from induced hypothermia to 10°C and lower has been reported.[67] Finally, accidental hypothermia is often complicated by immersion or drowning, prolonged fasting and/or hypovolemia, extreme exertion or exhaustion, trauma, or a variety of other clinically relevant conditions.

TREATMENT OF HYPOTHERMIA

Supportive care for the previously mentioned physiologic perturbations should be provided, and hypothermic patients should be protected from further heat loss with insulation and/or a vapor barrier, and they should be transferred to a controlled clinical setting when available. Intrinsic thermoregulatory responses should be addressed, including the vasoconstrictive sympathetic response in the skin and shivering in the muscles (primarily truncal muscles), which can both be stimulated by skin or core cooling. Shivering effectively provides heat at the expense of increased metabolic requirements that cannot be indefinitely maintained.[68] Similarly, after provision of caloric supplementation to support increased metabolic requirements, and taking steps to prevent a further drop in temperature, exercise is recommended to augment rewarming in the case of mild accidental hypothermia where neurologic function is intact.[69] Physiologically, shivering is blunted by exertional fatigue (termed thermoregulatory fatigue), hypoglycemia, and paradoxically, shivering is markedly attenuated and eventually stops as core temperatures continue to fall (<~31°C).[70] It may be undesirable in some clinical situations, and can be treated with a number of interventions, pharmacologic and otherwise.[64]

The vasoconstrictive sympathetic response protects from heat loss during cold exposure, but also impairs effectiveness of transcutaneous warming. On application of external heat, local vasodilation does occur despite continued core hypothermia.[71] Cutaneous warming can be applied using large heat packs (primarily in prehospital settings), or with forced air or circulating water devices when more advanced care is available. Radiant or resistive heating devices are less commonly used. Limitations to all of these methods include the potential for tissue damage from heat application (and therefore their maximum safe set temperature), and their reliance on effective peripheral circulation to distribute heat from the periphery to the core. Regarding the latter point, cutaneous warming is significantly more effective when applied to areas of skin with optimal blood flow; that is, in nondependent areas that are not compressed by body weight.

As mentioned, cutaneous warming demonstrates improved heat transfer efficiency with peripheral vasodilation. General anesthesia and some sedative medications can also affect peripheral vasodilation, which can exacerbate cooling in the context of exposure to cold environments, but in the context of cutaneous rewarming can similarly increase the effectiveness of warming, if vasodilation is not already maximal. On the other hand, vasodilation also makes simultaneous cooling across exposed skin possible, even with warming devices covering other locations. Efforts should be made to cover or warm as much exposed skin as possible in patients under anesthesia (and those sedated using vasodilating agents) to prevent this inefficiency.

Administered fluids should be warmed, which is of increasing importance with administration of large volumes such as in severe diuresis, dehydration, or traumatic blood loss. However, administration of warmed fluids rarely actively warms patients to any important extent because of the small amounts given relative to the heat distribution volume in most patients, and because it is unsafe to heat fluids much above normal body temperature. Similarly, airway heating and humidification can result in environmental heat loss. Provision of heated, humidified oxygen can prevent further heat loss, but its capacity for heat exchange is limited and it should only be used in conjunction with other warming methods.

A number of invasive warming methods have been used, including heat exchange through intravascular warming catheters; hemodialysis circuits; and peritoneal, gastric, bladder, or pleural lavage. Increasing invasiveness generally also predisposes to potential for complications; primarily it should be kept in mind that some of these methods can negatively impact the circulation (i.e., impaired preload, bleeding) and precipitate circulatory collapse in at-risk patients. In general, all of these rewarming methods rely on the circulation for heat equilibration, and prolonged CPR may be logistically difficult or have limited effectiveness. Therefore, in the case of arrested, severely compromised, or at-risk circulation, an increasing number of centers report and recommend the use of extracorporeal life support (ECLS) for both circulatory support and controlled rewarming in patients with profound hypothermia (typically core temperature < 30°C).[54] As expected, these methods are not without pitfalls, but they can make resuscitation possible in extreme cases.[72] Rewarming for these methods is relatively rapid, and is primarily limited by standard guidelines for (1) temperature gradients between blood return and patient blood of greater than 10°C, to avoid outgassing and generation of gaseous emboli when blood is returned to the patient; and (2) an upper threshold of 37°C for outlet blood temperature to avoid cerebral hyperthermia.[73]

Finally, it is worth reviewing issues that present in the setting of hypothermia that may complicate the rewarming process. The most important are the concepts of rescue arrest and afterdrop. Hypothermic patients are likely to be hypovolemic and to suffer from acidosis and electrolyte abnormalities, and are predisposed to significant cardiac arrhythmias. As such, changes in posture that impact preload, or significant vasodilation that may occur on initiation of cutaneous rewarming can contribute to cardiovascular collapse. Peripheral vasodilation or improvement in tissue hypoperfusion can also allow accumulated metabolic byproducts to enter the circulation and exacerbate acidosis. Afterdrop refers to the phenomenon of continued core cooling even after rewarming has been initiated, due to continued loss of heat from the core to the cool periphery. In general, as rewarming progresses, clinical and laboratory parameters must be followed closely to avoid overcorrection, particularly in the case of pH or temperature-dependent phenomenon such as insulin sensitivity.

HYPOTHERMIA OUTCOME

Outcome after treatment of hypothermia is highly dependent on whether there has been coincidental trauma, cardiac arrest, significant hypoxia, or advanced age, all of which adversely affect prognosis.[54] On the other hand, resuscitation from hypothermia with intact cardiac activity (core temperature typically > 28°C) has low mortality. Of a series of 1028 children admitted to hospital with accidental hypothermia, 91.5% survived.[74] In a study of 572 adults with accidental hypothermia (core temperature ≤ 32°C), 83% of patients younger than 75 survived to hospital discharge.[75]

Hyperthermia

PHYSIOLOGY OF HYPERTHERMIA

Optimal physiologic and biochemical homeostasis requires regulation of body temperature within a narrow range, typically 36.7°C to 37.5°C. Heat is generated by metabolism, which can vary several-fold from resting during sleep to heavy exercise. Internally generated heat is dissipated through the skin by conduction, radiation, convection, and evaporation of sweat. In an environment where ambient temperature is greater than skin temperature (typically around 33°C), heat is gained from the environment, allowing only sweating as a mechanism for maintenance of normal body temperature. Adaptation to hot environments (acclimatization) can occur over days or weeks. Mechanisms of acclimatization include increased blood volume and body water, lower body temperature, enhanced skin vasodilatation and sweating, and production of a more dilute sweat.[76]

When core temperature increases, the normal adaptive response is cutaneous vasodilatation and initiation of sweating. There is redistribution of cardiac output to the skin, with concomitant reduction in splanchnic and renal blood flow,[77] which can lead to gut, liver, and kidney ischemia. Dehydration and the resulting hypovolemia attenuate the increase in skin blood flow and accentuate splanchnic vasoconstriction. With continued hyperthermia, a nitric oxide-mediated mechanism causes vasodilatation in the splanchnic bed, which can precipitate hypotension and shock,[78] and possibly gastrointestinal ischemia-reperfusion injury.[79]

Heat-induced cell damage occurs at temperatures beyond a threshold that is species-specific. In humans, the critical temperature is between 41.6°C and 42°C sustained for 0.75 to 8 hours.[80] The major mechanism for body injury from high temperature is damage to macromolecules, including lipids, DNA, and proteins. Temperature increases can cause oxidative stress, protein unfolding, entanglement, and aggregation.[79,81] Uncoupling of oxidative phosphorylation and a reduction in mitochondrial number lead to a decrease in adenosine triphosphate (ATP) levels. In parallel with physiologic adaptive mechanisms, there is a cellular stress response (CSR), which is triggered by accumulation of damaged macromolecules.[79,81] The CSR consists of altered gene expression that initiates the production of a series of heat shock proteins (HSPs) that falls into seven categories.[81] The major HSP group consists of what are referred to as ''molecular chaperones.'' These chaperone proteins recognize unfolded proteins and either refold them into their normal functional state or direct them into degradation pathways. Another group of HSPs is proteolytic, which clear irreversibly damaged proteins. A third group facilitates DNA and ribonucleic acid (RNA) damage. A fourth group consists of enzymes that facilitate re-establishment of metabolic pathways after heat stress. A fifth group includes regulatory proteins. The sixth category comprises proteins involved in sustaining cellular structures such as the cytoskeleton. The final category consists of proteins that facilitate transport, detoxification, and membrane-modulation.

CLINICAL SCENARIOS

Definitions. *Heat exhaustion* is a mild form of heat illness that is notable for inadequate cardiac output accompanied by elevated body temperature, dehydration, and hot, dry skin. Symptoms include fatigue, dizziness, nausea and vomiting, headache, and hypotension.[82] Heat exhaustion occurs in hot environments, often precipitated by exercise. It can also be precipitated by some medications such as diuretics and inadequate water intake, often in older adults.[82] Body temperature in heat exhaustion is usually between 37°C and 40°C.[83] *Heat injury* is more severe than heat exhaustion and after some hours may include some organ and tissue damage.[82] If patients with heat injury are not rapidly cooled the condition may worsen to *heat stroke*, which is life-threatening. Heat stroke is commonly classified as *exertional* or *classic*. Exertional heat stroke usually occurs in young healthy individuals who are exercising in hot environments, often presenting with collapse. Classic heat stroke usually occurs in very young or older individuals exposed to a hot environment without strenuous physical activity.[79,82]

Manifestations of heat stroke include hot dry skin, weakness, anorexia, dizziness, syncope, nausea and vomiting, headache, and confusion. Neurologic manifestations in heat stroke include mental status changes, delirium, coma, and convulsions, but there is often a lucid interval during which the patient may have normal mental status despite severe temperature elevation.

Body temperature in heat stroke is generally in the range of 40°C to 44°C, although temperatures extending from mild elevation to above normal to 47°C have been reported.[79] Differentiating heat stroke from exercise-related heat exhaustion requires assessment of body temperature. Sensors placed on or close to sites on the exterior of the body (e.g., axillary, oral, tympanic, and skin) are not valid during or after intense exercise in the heat. The only adequate measurement sites in this setting are from sensors in the rectum or via radio telemetry from pre-ingested thermistor capsules.[82,84,85]

Metabolic acidosis occurs in the majority of cases of severe heat stroke, especially in exertional heat stroke, often accompanied by respiratory alkalosis.[82,86,87] Rhabdomyolysis, hyperkalemia, and disseminated intravascular coagulation are common. Renal failure commonly occurs in exertional heat stroke, but not classic heat stroke. Hyperglycemia and hypophosphatemia are common in classic heat stroke, whereas biochemical features in exertional heat stroke include hyperphosphatemia, hypocalcemia, and hypoglycemia.

The differential diagnosis of heat stroke includes status epilepticus, stroke, and drug use (including recreational drugs, antidepressants, antihistamines, and antiparkinsonian drugs).[79] Another life-threatening condition that can be confused with heat stroke is exercise-associated hyponatremia (EAH). This condition, which occurs during prolonged exercise, has manifestations similar to heat shock: lightheadedness, nausea, headache, vomiting, altered mental status, and collapse but often without hyperthermia. When these signs and symptoms occur during prolonged exercise it is essential to exclude EAH as its treatment requires correction of serum sodium.[88] When hyperthermia occurs in the perioperative environment, possible diagnoses include malignant hyperthermia (MH), neuroleptic malignant syndrome (NMS), thyroid storm, and serotonin syndrome. Assessment of MH is described in Chapter 35. NMS is manifested by muscle rigidity, fever, mental disturbances such as delirium and abnormal metabolic changes in patients treated with classic triggering agents such as antipsychotic drugs (e.g., phenothiazines, butyrophenones, lithium), metoclopramide, antidepressants, and some anticonvulsants.[89] In addition to fever, manifestations of serotonin syndrome include clonus, agitation, tremor, muscle rigidity, and hyperreflexia in patients taking serotonergic medication.

TREATMENT OF HYPERTHERMIA

As in the treatment of hypothermia, supportive care to correct physiologic derangements and potential complications is as vital as rapid correction of the core temperature. Fluid management is a primary consideration in virtually any hyperthermic patient, with the degree of perturbation dependent on the heat source, duration of exposure, and amount of sweating. Electrolyte depletion from sweating may also be profound, and hypercalcemia, hyper- or hypokalemia, hypophosphatemia, or hyper/hypoglycemia may require correction in hyperthermic patients.[82]

The underlying cause of hyperthermia determines therapeutic options, and also impacts the effectiveness of selected cooling methods. Cooling in any hyperthermic patient should be expeditious to limit further organ damage, but ongoing excessive metabolic heat generation must also be addressed for cooling to be effective.

Fever induced by immunologic reaction may be responsive to antipyretics or antiinflammatory medications, and discontinuation of a fever-inducing medication or toxin is an obvious first step. Seizures or shivering can contribute significantly to hyperthermia, and a number of therapeutic options exist.[64] In these conditions, pharmacologic treatments may be combined with cooling, depending on the degree of hyperthermia. Treatment of MH is described in Chapter 35. NMS is treated by discontinuation of suspected triggering drugs and supportive care. Pharmacotherapy may include dantrolene, bromocriptine, and amantadine.[89] Treatment of serotonin syndrome also includes discontinuation of triggering agents, supportive care, and administration of a 5-HT$_{2A}$ antagonist such as cyproheptadine,[90] and possibly benzodiazepines. For heat stroke there is no recommended pharmacologic treatment (due to concerns for hepatic toxicity). Nonsteroidal antiinflammatory drugs (NSAIDs) and aspirin are ineffective, and acetaminophen is contraindicated (see earlier).[79,82] Dantrolene is ineffective in heat stroke.[91]

Heat exhaustion usually responds to simple methods of cooling such as moving to an air-conditioned space, removal of excessive clothing, and application of cloths soaked in cool water. Hyperthermia in heat stroke is managed by institution of cooling as quickly as possible, combined with supportive treatment. The target to which cooling should be pursued is not well-supported by evidence, but many studies have used a target of less than 39°C rectal temperature.[92] Ice water immersion and evaporative cooling are among the most effective noninvasive cooling methods, but they are not always logistically feasible, including in clinical settings where there are concerns for infection or significantly compromised integrity of the skin (e.g., dressings, burns, line sites). Ice packs (with a skin barrier to avoid direct contact and risk of tissue injury) can be applied to central areas with good blood flow, such as the groin, axillae, neck, and torso. All of these methods require ongoing refreshment of the cold source to maintain an effective temperature gradient, and attention to the skin at the site of application to avoid cold injury to tissue is critical. Adhesive cold-water circulating devices are contained, provide continuous refreshment of the temperature gradient, and may be equipped with thresholds and alarms to provide some margin of safety from cold injury. But, as in the case of cutaneous warming, adhesive pads require large areas of intact skin with good blood flow for effective use. These transcutaneous cooling methods all depend on cutaneous vasodilation for effective heat transfer from the core. But with cutaneous cooling, local vasoconstriction and shivering can be induced if temperatures are sufficiently low. Inhibition of shivering or vasoconstrictive responses, as previously discussed, may be used to offset these effects.

Effective but increasingly invasive cooling methods include bladder, gastric, or colonic irrigation with cold saline, intravascular cooling catheters, and administration of cold intravenous fluids.[82,93] Immersion in ice water is safe and effective in young individuals suffering from exertional heat stroke; however, in classic heat stroke it is poorly tolerated and may be associated with increased morbidity and mortality.[79] As in the case of hypothermia treatment, the effectiveness of cold intravenous fluids is limited by concerns for overexpansion of intravascular volume, although the temperature gradient that can be achieved is larger than that for warmed fluids for treatment of hypothermia; cold fluids can be near 4°C, as opposed to warm fluids, which must be near 37°C to avoid local hyperthermia. For patients requiring ECLS (or ECMO), some degree of cooling can be achieved passively due to blood volume flowing through external circuit components. It is noteworthy that while it is common for extracorporeal support circuits to be equipped with heat exchangers to warm the blood, some lack the ability to provide monitored active cooling (as opposed to cardiopulmonary bypass circuits, in which cooling capability is a standard feature). If cooling is a therapeutic goal, this should be considered at the time of circuit choice if there are multiple options available.

After cooling and successful resolution of hyperthermia, clinicians must continue to be vigilant for (1) hypothermia due to aggressive cooling or a dysregulated thermoregulatory response; (2) recurrent hyperthermia; and (3) the development and secondary effects of organ injury that occurred when body temperature was elevated.[82] Short- and/or long-term lung, kidney, liver, cardiovascular, and neurologic injuries have all been described after heat stroke.

HYPERTHERMIA OUTCOME

After cooling, sequelae can include ongoing encephalopathy, seizures, liver failure, renal failure, and adult respiratory distress syndrome (ARDS). Recurrent fever is common during recovery, does not respond to aspirin or NSAIDs, and may further exacerbate brain injury. Acetaminophen is sometimes prescribed but has been associated with liver failure and is contraindicated.[79,82]

Mortality in exertional heat stroke is reported as 3% to 5%.[79] As many as 60% of patients with classic heat stroke die before reaching the hospital, thus it is difficult to determine the true mortality. Of those who are admitted to an ICU, in-hospital mortality is 10% to 65%, however there is also 10% to 28% mortality at one and two years after treatment. Persistent neurologic manifestations including

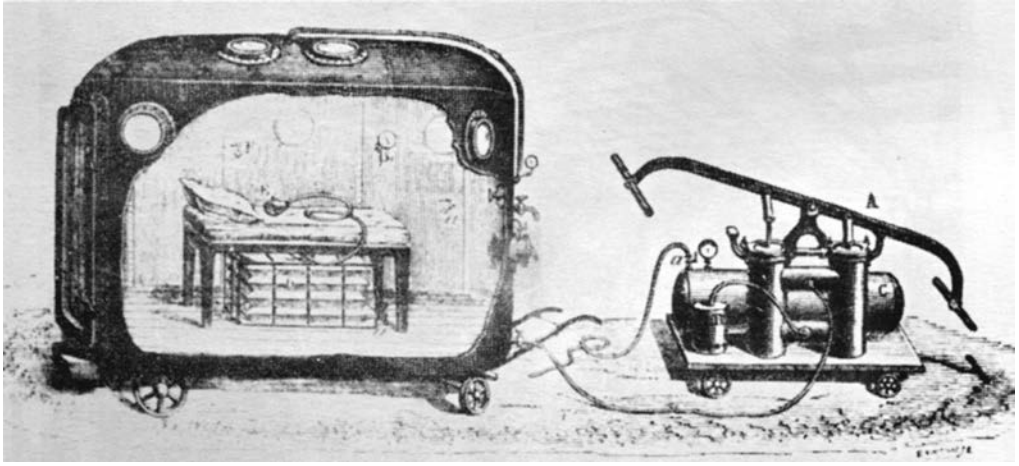

Fig. 75.4 Mobile hyperbaric operating room described by Fontaine in 1879–1895. Nitrous oxide storage tanks can be seen under the operating table. Compressed to 1.25 to 1.33 atmospheres absolute with air, a nitrous oxide-oxygen mixture was provided to the patient. Breathing air in this chamber would have provided an inspired partial pressure of oxygen (PO_2) equivalent to 26% to 28% O_2 at 1 ATA. (From Fontaine J-A: Emploi chirurgical de l'air comprimé. L'Union Médicale: journal des intérêts scientifiques et pratiques moraux et professionnels du corps médicale Paris. 28 [Ser 3]:445-448, 1879. Reprinted with permission of the New York Academy of Sciences.)

ataxia, dysarthria, and problems with coordination occur in a high percentage of patients and are associated with imaging abnormalities such as cerebellar atrophy.[79,82,87,94]

Effects of Increased Gas Pressure

HISTORY

Compressed air technology was developed in the 19th century, which led to men working in compressed air environments for bridge and tunnel construction. Surface-supplied compressed air, and later self-contained compressed air breathing apparatus (scuba), allowed divers involved in the collection of sponges, pearls, and ship salvage to spend significant periods of time breathing air under pressure. New occupational diseases due to in situ formation of bubbles from inert gas supersaturation and pulmonary barotrauma were described: respectively, DCS and arterial gas embolism (AGE). The technology was in an attempt to treat a variety of diseases without any plausible rationale. This included tuberculosis, heart failure, emphysema, bronchitis, asthma, croup, whooping cough, anemia, anorexia, dyspepsia, leucorrhea, menorrhagia, neuralgic pain, and depression. An exception was the use by Fontaine in 1879 of a mobile hyperbaric chamber for anesthesia and surgery.[95] Compressed to 1.25 to 1.33 atmospheres absolute (ATA), a nitrous oxide–O_2 mixture was provided to the patient (Fig. 75.4). Breathing air in Fontaine's chamber would have provided an inspired partial pressure of O_2 (PO_2) equivalent to 26% to 28% O_2 at 1 ATA. This was probably the first use of an elevated PO_2 during anesthesia and certainly the first administration of hyperbaric nitrous oxide.

Use of O_2 at high pressure for the treatment of DCS had been proposed[96] and later reported for the treatment of DCS,[97] but remained an isolated medical curiosity until the early 1960s. A few indications, such as support of oxygenation in hyaline membrane disease of the newborn[98] and during open heart surgery,[99,100] were not useful. For other indications, such as CO poisoning, AGE, and DCS, HBOT proved to be effective, as evidenced by substantial clinical experience and randomized controlled studies. Indications are reviewed regularly by the Undersea and Hyperbaric Medical Society (headquarters in Durham, NC). This medical organization publishes an extensive bibliography with a list of indications for hyperbaric oxygenation that is updated every 3 to 4 years.[101] Laboratory and clinical data support the use of HBOT for a select number of acute and chronic illnesses (Box 75.1), and anesthesiologists are often called on to provide care of patients in this unusual environment.

INCREASED BAROMETRIC PRESSURE EFFECTS

Some effects of altered ambient pressure are summarized in Fig. 75.5.

An increase in environmental pressure is accompanied by significant adiabatic heat production, whereas decompression generates cooling. This results in an increase in chamber temperature during compression, and cooling and precipitation of water droplets during decompression. These phenomena may limit the rate of compression in manned chambers in order to maintain temperature within a comfortable range.

During changes in ambient pressure, pockets of trapped gas will contract and expand on compression and decompression. Examples include gas in the middle ear and paranasal sinuses, intestinal gas, pneumothorax, and gas pockets within medical equipment, including monitoring and life-support systems. Changes in gas volume are inversely proportional to ambient pressure (Boyle's law):

$$PV = \text{constant}$$

such that at constant temperature, a doubling of environmental pressure (P) will cause the volume (V) of a gas-filled cavity to decrease by half. This effect also underlies one of the major beneficial effects of hyperbaric treatment of pathologic gas, as in AGE or DCS (see later).

A comparison of pressure units used clinically with those in common use in hyperbaric environments is shown in Table 75.2.

BOX 75.1 Selected Conditions for Which There Is Evidence of Hyperbaric Oxygen Treatment Effectiveness

Gas-bubble Disease

Air embolism*[180,187,302,303]
Decompression sickness*[180,187,304,305]

Poisoning

Carbon monoxide*[141,147-149,155,156,161,306]
Cyanide[141]
Carbon tetrachloride[307,308]
Hydrogen sulfide[141]

Infections

Clostridial myonecrosis*[205,207,208]
Other soft tissue necrotizing infections*[205,207,309-311]
Refractory chronic osteomyelitis*[101,198,312]
Intracranial abscess*[313,314]
Mucormycosis*[311,315,316]

Acute Ischemia

Crush injury*[317,318]
Compromised skin flaps*[319,320]
Central retinal artery occlusion, central retinal vein occlusion*[215,216,321,322]

Chronic Ischemia

Radiation necrosis (soft tissue, radiation cystitis, and osteoradionecrosis)*[101,323-325]
Ischemic ulcers, including diabetic ulcers*[101,111,326-330]

Acute Hypoxia

Exceptional blood loss anemia (when transfusion delayed or unavailable)*[101]
Support of oxygenation during therapeutic lung lavage*[209,210]

Thermal Injury

Burns*[331-335]

Envenomation

Brown recluse spider bite[336-338]

Miscellaneous

Idiopathic sudden sensorineural hearing loss*[217]

*Approved by the Undersea and Hyperbaric Medical Society as an appropriate indication for hyperbaric oxygen treatment.[101]

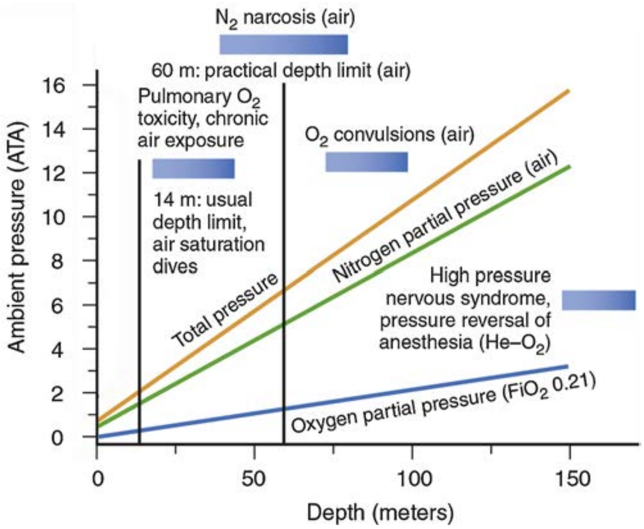

Fig. 75.5 Ambient pressure as a function of water depth. Ambient pressure increases linearly with depth, with pressure increasing by 1 ATM for each 10 m of depth. The oxygen partial pressure (PO_2) line is shown for a constant fraction of inspired oxygen concentration (FiO_2) of 21%. At increasing depth, inspired PO_2 eventually exceeds the pulmonary toxic limit (approximately 14 m in depth) and the central nervous system toxic limit (approximately 70 m in depth). The threshold for high-pressure nervous syndrome and pressure reversal of anesthesia (observed in nonnarcotic atmospheres, such as helium-oxygen) is 150 to 200 m depth. The shaded blue bars represent the depth or altitude ranges over which risk progresses from low *(light shading)* to high *(dark shading)*. *ATM,* Atmosphere; *He,* helium; *N$_2$,* nitrogen.

INCREASED PARTIAL PRESSURE OF OXYGEN

Breathing O_2 at increased ambient pressure will lead to elevation of alveolar O_2 tension (P_AO_2), which can be calculated according to the alveolar gas equation for O_2[102,103]:

$$P_AO_2 = F_IO_2(P_b - PH_2O) - P_ACO_2 \cdot \left(F_IO_2 + \frac{1 - F_IO_2}{R}\right)$$

where F_IO_2 is the fractional inspired O_2 concentration; PH_2O is saturated water vapor pressure at body temperature (typically 47 mm Hg); P_ACO_2 is alveolar partial pressure of CO_2 (PCO_2), assumed to equal arterial PCO_2 ($PaCO_2$); and R is respiratory exchange ratio (usually ≈0.8 at rest). Arterial PO_2 (PaO_2) at any given ambient pressure or FiO_2 can be estimated from arterial blood gases measured breathing air at atmospheric pressure by assuming that the arterial/alveolar (a/A) PO_2 ratio remains constant.[104,105]

TABLE 75.2 Units of Pressure

Atmospheres Absolute (ATA)	Absolute Pressure (mm Hg)	Gauge Pressure (mm Hg)	Feet of Sea Water (fsw)	Meters of Sea Water (msw)
1	760	0	0	0
2	1520	760	33	10
3	2280	1520	66	20
6	4560	3800	165	50

Whereas at 1 ATA the fraction of O_2 in arterial blood that is carried dissolved in the plasma is minimal, at an elevated PaO_2 in the range of 1000 to 2000 mm Hg, significant quantities of O_2 may exist in dissolved form (Table 75.3).

Increased PaO_2 has at least four pharmacologic effects:

1. Increased blood O_2 content
2. Vasoconstriction[106]
3. Antibacterial action, particularly against anaerobic bacteria[107]
4. Inhibition of endothelial neutrophil adhesion in injured tissue[108,109]

The increased arterial O_2 content underlies the rationale for administering HBOT for the treatment of ischemic conditions, for example, wounds that fail to heal due to insufficient blood supply. Elevated PaO_2 leads to an increase in tissue PO_2, which can be estimated using transcutaneous PO_2 electrodes.[110,111] The second effect, vasoconstriction, is an explanation for the effectiveness of HBOT in the treatment of traumatic edema (e.g., crush injury). The mechanism of HBOT-induced vasoconstriction appears to be inactivation of nitric oxide as a result of increased production of superoxide[112] and possibly decreased release of nitric oxide from circulating S-nitrosohemoglobin.[106,112,113]

These two effects, increased O_2 content and vasoconstriction, lead to hemodynamic changes,[106,114] shown in Table 75.3. There is also a slight increase in mean arterial pressure. Studies of HBOT effects on myocardial contractility using denervated hearts[115] or autonomically blocked animals[116] have indicated no intrinsic effect. In intact animals or humans, heart rate and cardiac output are decreased and systemic vascular resistance is increased.[106,114,117] In both anesthetized dogs and awake humans, pulmonary vascular resistance is decreased.[106,118] At 2 ATA, 100% O_2 in conscious dogs has no effect on coronary flow,[117] whereas at 3 ATA, both coronary flow and myocardial O_2 consumption are decreased.[116] Cerebral blood flow is decreased by O_2 administration over a range of pressures,[112,117] whereas at 2 ATA, hepatic, renal, and mesenteric flows are unchanged.[117] HBOT also has microcirculatory and cellular effects in various disease states (see later).

ELEVATION OF INERT GAS PARTIAL PRESSURE

Elevation of the partial pressure of the inert gas (usually nitrogen) present in a breathing mixture is associated with a narcotic effect, predictable by the Meyer-Overton hypothesis. Based on its solubility in olive-oil, nitrogen has 0.03 to 0.05 times the narcotic potency of nitrous oxide. At 3 to 4 ATA (breathing air), most people experience mild euphoria. At 6 ATA, there may be memory loss and poor judgment. At 10 ATA, some individuals lapse into unconsciousness. Nitrogen narcosis has been compared with alcoholic intoxication, with each increase in ambient pressure of 1.5 ATA breathing air resulting in an effect that is said to be similar to drinking one martini. Argon and to a lesser degree hydrogen are also narcotic, whereas helium has minimal if any narcotic effect. In animals exposed to high partial pressures of nitrogen, there is evidence of activation of $GABA_A$ receptors of dopaminergic neurons in the nigrostriatal pathway, leading to a decrease in dopamine release.[119]

ELEVATION OF ABSOLUTE PRESSURE

High-Pressure Nervous Syndrome

High pressure induces a constellation of symptoms consisting of tremor, ataxia, nausea, and vomiting that is known as the high-pressure nervous syndrome (HPNS).[120] It occurs at an ambient pressure greater than 15 to 20 ATA and was first described during the compression phase of deep dives with a helium-O_2 atmosphere. HPNS is attenuated by slow compression and addition of a narcotic gas (e.g., nitrogen) to the breathing mix.[121] Its pathogenesis may be related to an increase in striatal dopamine.[122]

Pressure Reversal of Anesthesia

Studies in animals have demonstrated that high pressure has the tendency to reverse general anesthesia. Elevations in ambient pressure in the absence of a narcotic inert breathing gas will tend to decrease the effectiveness of both inhaled and intravenous anesthetics. At 50 ATA, a 20% increase in the 50% effective dose (ED_{50}) occurs in mice with a variety of inhaled anesthetics. At 50 and 100 ATA, the effective dose of barbiturates increases by 30% to 60%.[123] The ED_{50} for diazepam in rats is markedly reduced at 90 ATA in a helium-O_2 atmosphere.[124] At 31 ATA, the effective concentration for half-maximal effect (EC_{50}) of propofol for loss of righting reflex in tadpoles is increased by 19%, and at 61 ATA, by 38%.[125] Using the same technique, the EC_{50} for dexmedetomidine at 31 ATA is nearly double the value at 1 ATA, and it is increased 2.5-fold at 61 ATA.[126] At 80 ATA, the MAC of desflurane as assessed by response to a noxious stimulus is increased by 19%.[127] The mechanisms of pressure reversal are not fully understood, but may be secondary to physical chemical effects of pressure on membranes[128] or may be related to alterations in neurotransmitter release.[122] However, within the range of pressures used for HBOT (up to 3 to 6 ATA), the effects of pressure on sedative or anesthetic drugs are not clinically significant.

EFFECTS OF HYPERBARIC EXPOSURE ON DRUG DISPOSITION

A few studies have examined the disposition of drugs and drug effects at increased environmental pressures. Studies in awake dogs at pressures up to 6 ATA and ambient PO_2 up to 2.8 ATA have shown that liver plasma flow decreased when either ambient pressure or PO_2 was increased. There was an apparent increase in plasma volume at 1.3 ATA and a return toward 1 ATA values at higher pressures. In the same studies plasma volume was inconsistently affected by ambient pressure, but reduced by increases in PO_2.[129]

There is no major pharmacokinetic or pharmacodynamic effect of hyperbaric exposure for most drugs up to 6 ATA. Pharmacokinetic studies of a few drugs have shown that up to 6 ATA pressure and 2.8 ATA PO_2, the pharmacokinetics of meperidine,[130] pentobarbital,[131] theophylline,[132] and salicylate[133] are unaffected.

Use of benzodiazepines, chlorpromazine, and lithium carbonate has been reported for the treatment of agitation, auditory and visual illusions, and paranoia in a previously normal subject participating in an experimental dive to 650 m (66 ATA).[134] The symptoms, poorly controlled with

diazepam 120 mg/day and temazepam 60 mg/day, ultimately responded to chlorpromazine 300 mg/day. Lithium carbonate administered in conventional doses appeared to display normal pharmacokinetics. Although the effect of chlorpromazine appeared clinically to be appropriate, the authors were uncertain as to whether the failure of benzodiazepines to elicit a desired therapeutic response was due to the patient's condition or to a pressure-reversal phenomenon.

In summary, clinical experience and the published literature indicate that for a variety of drugs administered under hyperbaric conditions at the pressures used for clinical treatment (up to 6 ATA), conventional parenteral drug dosing schedules are safe.

Hyperbaric Oxygen Therapy

RATIONALE FOR HYPERBARIC TREATMENT OF SELECTED ACUTE CLINICAL ENTITIES

Carbon Monoxide Poisoning

Hemoglobin (Hb) binds CO with an affinity much higher (by a factor of about 200) than that for O_2. This binding of CO with Hb to form carboxyhemoglobin (HbCO) has two major effects. First, the proportion of Hb that is occupied by CO molecules is unavailable for O_2 transport, resulting in a functional anemia. Second, the avidity with which the remaining Hb binds O_2 is increased (shift to the left of the Hb-O_2 dissociation curve).[135] The result of this is a decreased ability to unload O_2 from blood to tissue at the capillary level and therefore, a reduction in tissue PO_2. Previously it was believed that these effects were totally responsible for the toxicity of CO. However, evidence has since been presented to show that the binding of CO to intracellular pigments (e.g., cytochrome a, cytochrome a_3, myoglobin) and oxidative stress may contribute significantly to the toxicity of CO.[136-144] CO exposure also triggers intravascular platelet-neutrophil aggregation and neutrophil activation.[144] These mechanisms result in toxicity to multiple organ systems, including brain and heart.[141,145] Immune-mediated effects have also been described.[146]

Clinical effects include headache, nausea, vomiting, dizziness/ataxia, myocardial ischemia, loss of consciousness, and, during pregnancy, fetal distress. Persistent or delayed neurologic sequelae can occur, often after a clear window of lucidity.[147,148] Increased risk factors for persistent sequelae include older age (≥36 years) and longer CO exposure.[149]

The diagnosis of CO poisoning is made by a history of exposure (internal combustion engine exhaust, fire, improperly adjusted gas or oil heating, charcoal or gas grills, or exposure to paint stripper containing methylene chloride, which is metabolized by the liver to CO). Confirmation of the diagnosis is made by finding an elevated HbCO level in either arterial or venous blood. HbCO concentration is stable for several days in anticoagulated blood samples. Therefore, if HbCO determination is not available at a referring facility, the diagnosis can be confirmed using a blood sample obtained at the time of initial evaluation and transported with the patient. Fetal hemoglobin (HbF) can produce a falsely elevated reading for HbCO on certain four-wavelength laboratory co-oximeters.[150] In the first few weeks of life, blood from normal infants may therefore falsely indicate 7% to 8% HbCO.

Actual HbCO levels measured on arrival in the emergency room correlate poorly with clinical status and should not be used as the sole criterion to determine the need for treatment. Because of the lower intracellular PO_2, elimination of CO from intracellular binding sites occurs more slowly. Significant mental obtundation, vomiting, and headache may remain even in patients with a normal HbCO level.

Brain imaging may reveal a variety of abnormalities in patients with CO poisoning, including hypodensities in the globus pallidus and subcortical white matter, cerebral cortical lesions, cerebral edema, hippocampal lesions, and loss of gray matter/white matter differentiation, and white matter hyperintensities.[151-153] Except to exclude other pathologic processes, brain imaging is not useful for determining who should receive HBOT, but it may provide prognostic information. Lesions in both globus pallidus and white matter are associated with poor long-term outcome.[151,154]

O_2 is the primary treatment modality for CO poisoning. High PaO_2 hastens the removal of CO from blood, as indicated by a reduced half-life of HbCO. Fig. 75.6 shows the HbCO half-time in a series of CO-poisoned patients during normobaric O_2 administration; HBOT reduces the half-time even further, to around 20 minutes at 2.5 ATA.[155] Additionally, the increased dissolved O_2 in plasma may support tissue oxygenation pending removal of CO from Hb and other proteins important for O_2 transport. Mounting evidence indicates that for poisoning in which neurologic symptoms occur, HBOT may decrease both early and late morbidity.[156] Although the results of one randomized prospective trial of hyperbaric versus normobaric oxygen revealed no apparent benefit of HBOT,[157] in four other trials HBOT resulted in improved outcome compared with treatment at 1 ATA (Fig. 75.7).[147,148,158,159] HBOT has been observed to reduce mortality in CO poisoning.[160]

Commonly used guidelines for the application of HBOT in CO poisoning include the following:[161]

Neurologic impairment (including dizziness, loss of consciousness), even if the patient seems normal at the time of medical evaluation
Cardiac abnormalities (ischemia, arrhythmias, ventricular failure)
Metabolic acidosis (consider also concomitant cyanide poisoning)
HbCO level that has been greater than 25%

Fetuses are particularly susceptible to CO toxicity. Pregnant women who fulfill the criteria just listed or in whom there is fetal distress should be treated with HBOT. Case reports,[162-164] published series,[165,166] and a critical review[167] support the concept that inadequately treated CO poisoning is a serious risk to the mother and fetus, and the benefits of HBOT outweigh the theoretical risks to the fetus from HBOT. Potential adverse effects of currently implemented HBOT protocols have not been confirmed in clinical practice.

Gas Embolism and Decompression Sickness

Introduction of gas into the arterial circulation (AGE) has traditionally been associated with scuba divers and attributed to pulmonary barotrauma during ascent from a dive

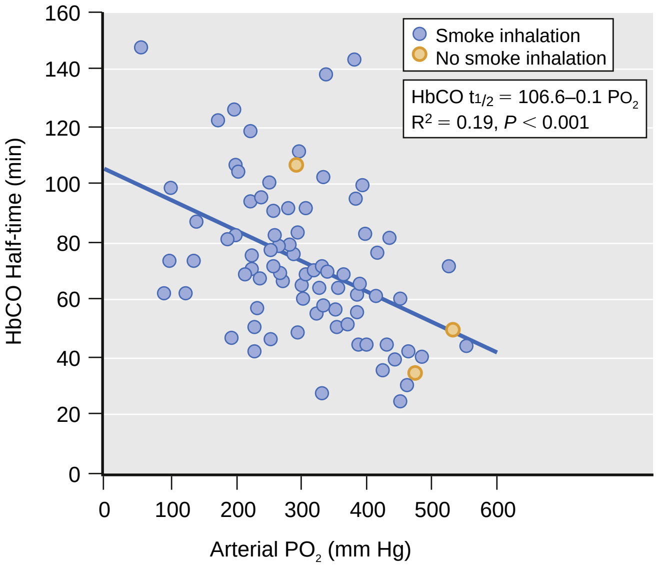

Fig. 75.6 Elimination half time of carboxyhemoglobin in 93 carbon monoxide-poisoned patients. Although there is scatter in the data, it is apparent that carbon monoxide dissociates from hemoglobin faster at higher partial pressure of oxygen *(PO_2)*. (Re-drawn from Weaver LK, Howe S, Hopkins R, Chan KJ. Carboxyhemoglobin half-life in carbon monoxide-poisoned patients treated with 100% oxygen at atmospheric pressure. *Chest.* 2000;117[3]:801–808.)

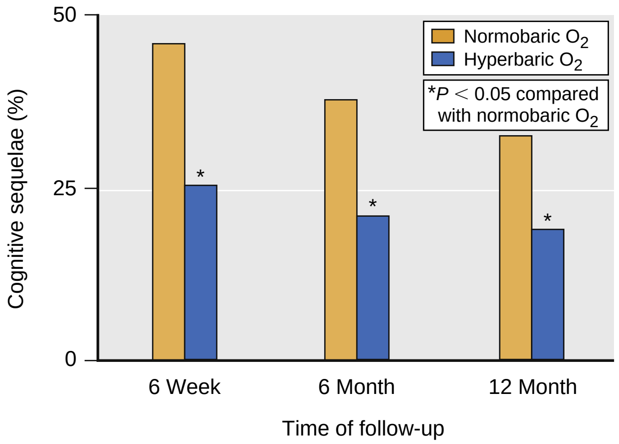

Fig. 75.7 Cognitive sequelae in a randomized prospective trial of hyperbaric oxygen (O_2) in carbon monoxide poisoning. Cognitive sequelae were defined as any T score for a neuropsychological subtest more than 2 standard deviations (SD) below the mean of demographically corrected standardized T scores, or if two or more T scores for subtests were more than 1 SD below the mean. If the patient reported difficulties with memory, attention, or concentration, then cognitive sequelae were defined as a T score on any neuropsychological subtest more than 1 SD below the mean of demographically corrected standardized T scores. (Drawn from data reported by Weaver LK, Hopkins RO, Chan KJ, et al. Hyperbaric oxygen for acute carbon monoxide poisoning. *N Engl J Med.* 2002;347[14]:1057–1067.)

while breathing compressed gas. However, it may also occur iatrogenically in several clinical circumstances, such as during cardiopulmonary bypass or as a result of inadvertent injection of air during a diagnostic arteriogram or hemodialysis. Additionally, large amounts of gas may enter the venous system, for example during neurosurgical procedures with the patient in the sitting position, accidental disconnection of hemodialysis access equipment, major back surgery, total hip replacement, cesarean section, laparoscopy, intrauterine laser surgery, arthroscopy (from air escaping from a faulty air-powered instrument), and hydrogen peroxide irrigation or oral ingestion (due to elaboration of gaseous oxygen from tissue and blood catalase). Venous gas embolism (VGE) can also occur when a central venous catheter is opened to air. Severe VGE has also occurred during orogenital sex after blowing air intravaginally.[168] VGE has been reported in patients with ARDS who are being ventilated with positive end-expiratory pressure (PEEP).[169] VGE in sufficient quantity may overwhelm the ability of the pulmonary vasculature to filter the gas, allowing bubbles to pass into the arterial circulation. Even small amounts of venous gas (e.g., VGE caused by decompression from diving) have recently been implicated in neurologic syndromes in scuba divers because of transatrial passage through a patent foramen ovale.[170,171]

The effects of gas embolism can be partly due to vessel obstruction by bubbles, but bubble-endothelial interaction causes increased capillary permeability and extravasation of fluid,[172-174] resulting in hemoconcentration. Impaired endothelial function also occurs.[175] Another effect has been demonstrated in a model of AGE in anesthetized rabbits[176,177]: small doses of intracarotid air may pass through the cerebral microcirculation yet produce vasoplegia, delayed reduction of cerebral blood flow, and neurophysiologic impairment. This reduction in blood flow is abolished when there is neutropenia; thus it has been concluded that leukocytes are a major component of the pathophysiology.[178] This phenomenon of delayed reduction of cerebral blood flow may be responsible for the clinical observation of initial neurologic improvement after AGE, followed by delayed deterioration.[179]

A related syndrome that results from pathologic effects of tissue and blood gas bubbles is DCS, seen in aviators and compressed gas divers. The gas bubbles in these situations occur because of a decrease in ambient pressure at a rate sufficient to induce local inert gas supersaturation, resulting in formation of bubbles *in situ* from tissue stores. Manifestations of AGE classically consist of impaired consciousness, hemiparesis, or seizures, but may be of a less severe nature. DCS most commonly presents as any combination of joint pain, paresthesias, motor weakness, bladder or bowel sphincter dysfunction, vertigo, tinnitus, and hearing loss.[180,181]

Treatment principles for both forms of gas bubble disease, AGE and DCS, are the same in most instances. First aid includes therapy with O_2.[182] High PO_2 results in an increased rate of resolution of gas bubbles because of the resulting higher partial pressure gradient for diffusion of inert gas from the interior of the bubble into the surrounding tissue or blood. Fluid resuscitation will replenish intravascular volume, relieve hemoconcentration, and facilitate microcirculatory flow,[183] principles that have been confirmed by both animal[184] and human observations.[173] However, excessive fluid administration can worsen pulmonary gas exchange in cardiorespiratory DCS (pulmonary edema from VGE), and aggressive fluid therapy is not indicated for isolated AGE.[183] Although capillary leak resulting from cerebral AGE can raise intracranial pressure, studies in anesthetized pigs have shown that hyperventilation is ineffective in reversing its effects.[185]

HBOT is the definitive treatment for AGE and DCS.[180] The increased pressure causes a diminution in gas volume and thus further hastens resolution. The usefulness of HBOT for diving-related or aerospace-related gas embolism associated with rapid decompression is well documented.[186-188] HBOT may effect neurologic improvement even after many hours and sometimes days between the embolic event and treatment,[189-191] although some evidence suggests that severe abnormalities are less likely to resolve if not treated promptly.[192] Treatment of AGE is usually performed at ambient pressures from 2.8 to 6 ATA (see the section "Hyperbaric Treatment Schedules").

The decision to administer recompression treatment should be based entirely on clinical evaluation.[180] The only appropriate role for brain or spinal imaging (e.g., computed tomography [CT], magnetic resonance imaging [MRI]) is to exclude other pathologic processes such as hemorrhage, and only if there is a high degree of suspicion that bubbles are not the cause of a patient's symptoms. Some authors have suggested that patients with AGE should only be treated with HBOT if CT of the brain reveals air.[193] However, brain and spinal cord imaging of patients with AGE or DCS is insensitive,[191,192,194,195] and the abnormalities on either CT or MRI are usually not specific. Neither the presence nor absence of intravascular gas predicts response to hyperbaric treatment.[191,192] Nuclear imaging of the brain using single photon emission tomography (SPECT) or positron emission tomography (PET)[196] does not provide clinically useful information in the management of patients with bubble-induced neurologic injury. If either AGE or DCS is suspected, HBOT should be initiated as soon as possible unless there is high suspicion of another condition that may require different treatment.

Acute Infections

Anaerobic bacteria are especially sensitive to increased tissue PO_2. High O_2 tensions inhibit clostridial α-toxin production.[197] Other mechanisms include reversal of hypoxia-induced neutrophil function,[198-200] enhanced macrophage interleukin-10 expression,[201] and antiinflammatory effects.[202-204] Evidence in favor of the use of HBOT in clostridial and non-clostridial infections is provided by clinical series and database analyses.[205-208]

Support of Arterial Oxygenation in Therapeutic Lung Lavage

HBOT is a safe and effective method of supporting arterial oxygenation during therapeutic lung lavage, during which oxygenation has to be maintained by the contralateral (non-lavaged) lung.[209,210] In the authors' experience of over 100 procedures, using this technique to treat arterial oxygenation has been uniformly successful with no complications specific to HBOT. A reversible simulation of pulmonary gas exchange during the lavage procedure can be provided by temporarily ventilating the lung to be lavaged with 5% to 6% O_2/balance nitrogen, which reduces PAO_2 in that lung to approximately the level of mixed venous PO_2 and confining O_2 exchange to the contralateral lung. Hypoxemia within 5 minutes is predictive of hypoxemia during the actual lavage.

Maintenance of Oxygen Transport in Severe Anemia

The ability of HBOT to increase arterial O_2 content in plasma to clinically useful levels may allow support of tissue O_2 delivery even without Hb. HBOT can therefore be used for temporary support of severely anemic patients pending availability of definitive therapy in the form of cross-matched blood.

Crush Injury

HBOT increases tissue oxygen tensions, reduces edema, and, consequently, increases blood flow through injured soft tissue and may mitigate ischemia-reperfusion injury.[211-214]

Central Retinal Artery Occlusion and Central Retinal Vein Occlusion

Central retinal artery occlusion (CRAO) and central retinal vein occlusion (CRVO) are uncommon but devastating conditions resulting in sudden painless vision loss, which is usually permanent and with poor outlook for recovery of vision. Intermittent HBOT can maintain viability of the retina via diffusion of oxygen from the choroidal vessels pending recanalization of the occluded vessel. Urgent HBOT should be considered for patients presenting within 24 hours of symptom onset.[215,216]

Idiopathic Sudden Sensorineural Hearing Loss

Sudden sensorineural hearing loss is defined as hearing loss of at least 30 dB identified at 3 or more consecutive frequencies that occur over a period of less than 72 hours. The pathophysiology is unknown but local hypoxia has been speculated as a possible cause. Empirical HBOT has been shown to offer benefit, with greater success when it is administered soon after symptom onset.[217,218]

THERAPEUTIC SYSTEMS

The traditional method of administering hyperbaric therapy is with a multiplace chamber, which accommodates two or more persons (Fig. 75.8). Size may vary from a small, portable 2-person chamber used for transporting patients in the field to one 20 feet or more in diameter, in which up to 12 or more patients may be comfortably treated, in addition to tenders (attendants). Multiplace chambers are compressed with air while the patient breathes O_2 with a head tent (Fig. 75.9), face mask, or endotracheal tube. Because of immediate access to the patient by accompanying nursing personnel or physicians, monitoring and resuscitative procedures are straightforward. However, multiplace chambers take up a significant amount of space and are expensive.

Monoplace chambers are large enough to accommodate only one patient (Fig. 75.10), or a tender with a small child. The chamber wall in most types is manufactured of Plexiglas, facilitating close visual observation of the patient. The chamber is usually compressed with 100% O_2. The advantage of monoplace chambers is their relatively low cost and ease of installation. Chamber operation can often be implemented by connecting the O_2 inlet to the hospital supply. Operation is relatively simple, but the patient inside is not directly accessible. Monitoring is somewhat more remote, and emergency airway management is not possible.

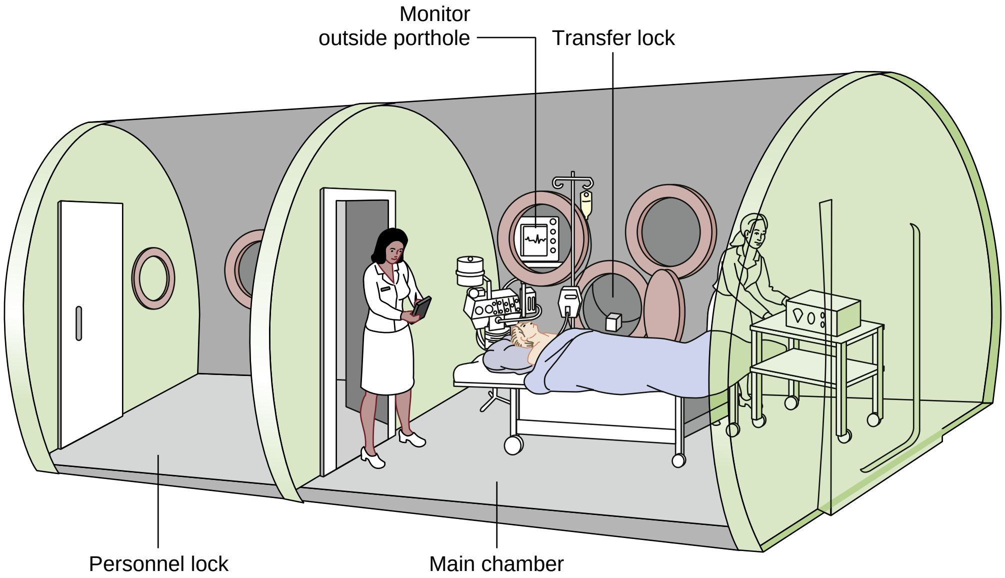

Fig. 75.8 Multiplace hyperbaric chamber large enough for one or more patients and tenders. The chamber atmosphere is compressed air. The patient receives 100% oxygen by mask, head tent, or endotracheal tube. Monitors are usually kept outside the chamber because of electrical safety considerations. Monitoring is possible through a porthole. A personnel lock and a transfer lock allow physicians, nurses, or other personnel, in addition to medications, food, and blood samples, to be moved into and out of the chamber without repeated compression and decompression of the patient.

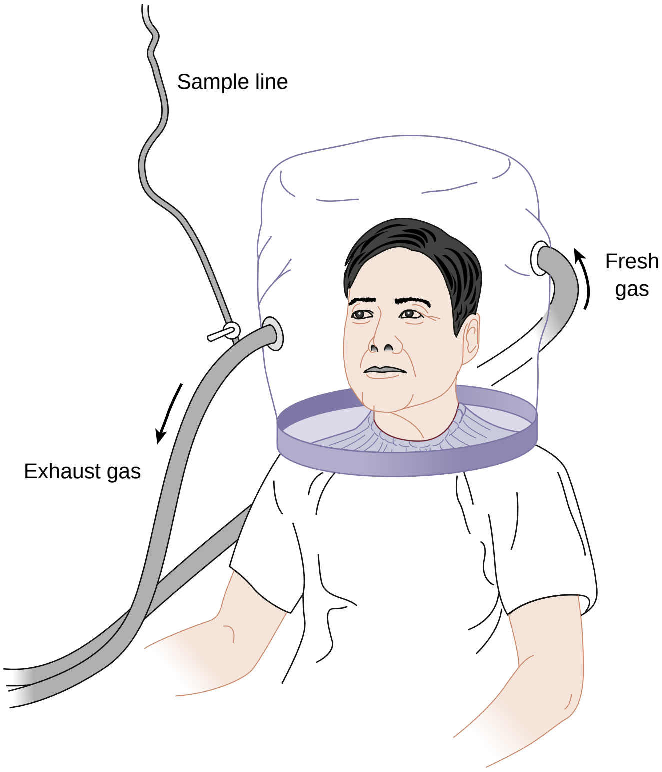

Fig. 75.9 Head tent circuit for use in a multiplace chamber. Fresh gas (100% O_2) flows at a constant rate (>30 L/min) through the head tent. Exhaust gas may be either vented outside the chamber or recirculated through a carbon dioxide scrubber. The sample line attached to the exhaust hose allows monitoring of the patient's breathing gas.

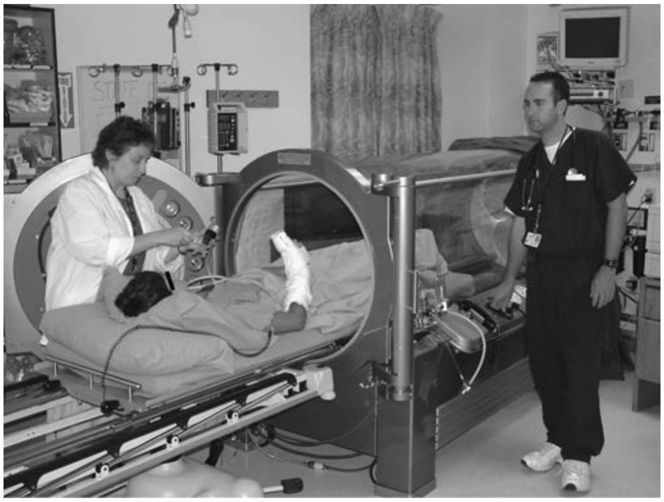

Fig. 75.10 Monoplace chamber. This type of chamber has room for one patient or a tender with a small child. The patient is moved into and out of the chamber on a wheeled gurney. The chamber atmosphere is usually 100% oxygen. The chamber is constructed of transparent Plexiglas to allow observation. Through-hull penetrators in the door on the left can be seen and allow monitoring, intravenous fluid administration, and control of a ventilator inside the chamber. (Photograph courtesy Dr. Lindell Weaver.)

Development of a pneumothorax during treatment, particularly a tension pneumothorax, can be fatal because pleural decompression with a needle or chest tube cannot be performed before decompression; however, this complication is extremely rare. A minor disadvantage of these chambers is that the ambient pressure limit is 3 ATA, and for practical reasons (psychological aversion to confinement) treatment times are limited. Moreover, intermittent periods of air breathing, to decrease the risk of O_2 toxicity during some types of treatment schedules (see later), requires installation of an additional gas delivery system. Nevertheless, monoplace technology now permits intravenous fluid administration from outside the chamber, invasive intravascular monitoring, mechanical ventilation, and utilization of pleural drainage systems incorporating regulated suction.[219,220]

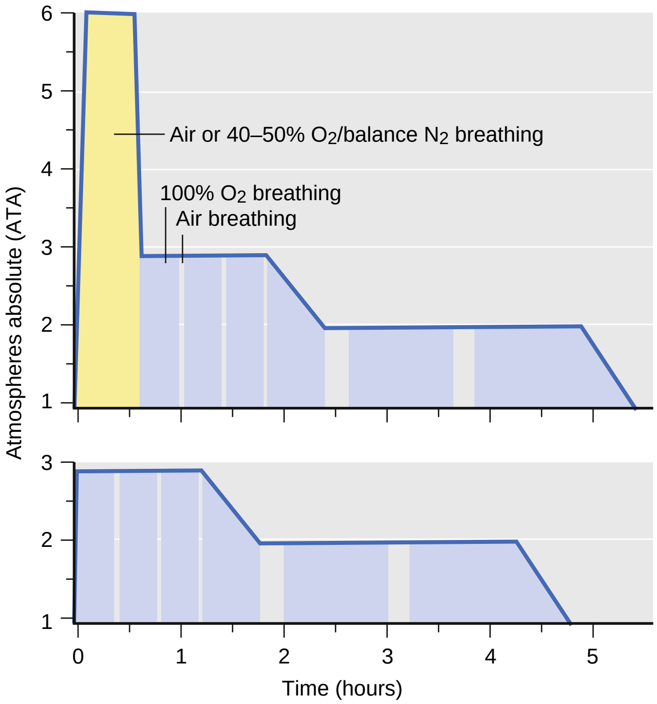

Fig. 75.11 US Navy treatment tables. (A) US Navy Table 6A. This schedule is occasionally used for the treatment of arterial gas embolism. During the 30-minute period at 6 atmospheres absolute, air or 40% to 50% oxygen (O_2) can be administered. (B) US Navy Table 6. This table was originally designed for the treatment of decompression sickness but is now the most commonly used table for gas embolism as well. The shaded areas represent 100% O_2 breathing; the white areas represent air breathing periods. Further details can be found in the US Navy Diving Manual. (From Navy Department. *US Navy Diving Manual. Revision 7. Vol : Diving Medicine and Recompression Chamber Operations. NAVSEA 0910-LP-115-1921.* Washington, DC: Naval Sea Systems Command; 2016.)

HYPERBARIC TREATMENT SCHEDULES

Ideally, a patient who has therapeutic indication for HBOT would be exposed for an unlimited time until the condition resolves. Unfortunately, several factors limit the dose and duration of HBOT:

O_2 toxicity
Decompression obligation for nursing staff (or other tenders) accompanying patient
Adequacy of monitoring
Patient isolation and boredom in a confined environment

Treatment schedules are compromises between O_2 partial pressure and exposure time on one hand and O_2 toxicity and other practical limiting factors on the other. The original schedules (or "tables") were developed by the various navies of the world to treat DCS and gas embolism in divers (Fig. 75.11).

U.S. Navy Table 6 (see Fig. 75.11) prescribes an initial exposure to 2.8 ATA (equivalent to 60 feet of sea water [fsw], or 18 m of sea water [msw]), followed by slow decompression to 1.9 ATA (30 fsw). Periods of O_2 breathing are interspersed with 5- or 15-minute periods of air breathing to decrease O_2 toxicity (see later). This schedule remains the mainstay of treatment for DCS in multiplace chambers throughout the world. Incomplete relief of signs or symptoms can be treated with repeated applications of U.S. Navy Table 6 or a shorter treatment on a once- or twice-daily basis.

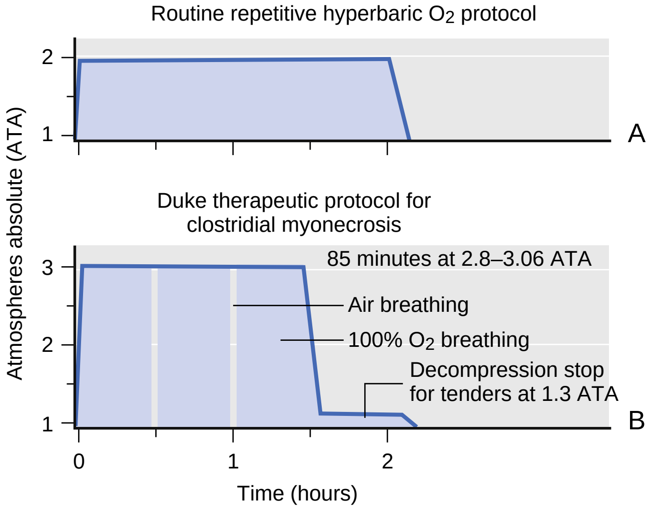

Fig. 75.12 Examples of clinical hyperbaric oxygen (O_2) treatment schedules. (A) The patient breathes 100% O_2 for 2 hours at an ambient pressure of 2 ATA. Generally, this schedule is used for repetitive treatment of chronic conditions (e.g., osteoradionecrosis). (B) Therapeutic schedule often used for treatment of clostridial myonecrosis. The patient and tender spend 85 minutes at 2.8 to 3.06 ATA (3 ATA shown). The patient breathes 100% O_2, except for two 5-minute air breaks to reduce pulmonary and central nervous system O_2 toxicity. A decompression stop is made at 1.3 ATA, according to the US Navy standard air decompression table. The stop is designed to facilitate safe decompression of the tender, who breathes air at 3 ATA. *ATA,* Atmosphere absolute.

"Saturation" treatment consists of an extended exposure to elevated pressure (e.g., 2.8 ATA) for an unspecified period of time (often 1 to 2 days) until manifestations have stabilized. Periodic O_2 breathing is given according to a recommended schedule as tolerated. Because saturation treatment results in a much larger degree of nitrogen uptake in both the patient and the tender, decompression must occur much more slowly, usually over 24 to 36 hours.[221] Although this therapy avoids the theoretical disadvantage of intermittent treatment—failure of resolution of gas bubbles—it is also considerably more labor intensive. Because hyperbaric chambers used for saturation treatments require additional hardware (e.g., CO_2 scrubbing capability) and personnel, their application outside military and commercial diving has been limited.

Examples of schedules used for treatment of patients with wound healing problems and with clostridial myonecrosis or other life-threatening anaerobic infections are shown in Fig. 75.12. The schedule for clostridial myonecrosis consists of 85 minutes at 3 ATA followed by a 33-minute decompression stop for the tenders at 1.3 ATA. This treatment schedule has been designed to maximize PaO_2 (and hence tissue bactericidal activity resulting from O_2) without an undue risk of hyperoxic seizures.

Treatment schedules for CO poisoning have varied. However, the proven efficacy of the schedule reported by Weaver (60 minutes at 3 ATA, 60 minutes at 2 ATA in addition to air breaks and compression-decompression time) supports the use of 3 ATA for at least the first treatment.[148]

Administration of HBOT to patients with chronic diseases (e.g., radionecrosis) is usually performed using shorter tables at lower ambient pressure, most commonly 1 to 2 hours at 2.0 to 2.5 ATA (see Fig. 75.9) once or twice daily. At this lower ambient pressure, the risk of O_2 toxicity is minimal and treatments are well tolerated by most patients.

SIDE EFFECTS OF HYPERBARIC OXYGEN THERAPY

Oxygen Toxicity

A wide body of evidence supports the notion that O_2 toxicity is caused by excessive production of oxygen free radicals (e.g., superoxide, hydroxyl radicals, and singlet oxygen). At high O_2 partial pressures, scavenging mechanisms can be overcome by increased rates of free radical production.[222] With the use of supplemental O_2 at 1 ATA, the manifestations of O_2 toxicity are almost exclusively confined to the lung; however, during hyperbaric O_2 exposure, other organs can be affected as well.

O_2 toxicity during HBOT can affect mainly the lung, the central nervous system (CNS), and the eye. Pulmonary toxicity in the conscious patient is heralded by symptoms of tracheobronchial irritation, namely, cough and burning chest pain. Prolonged exposure may result in a decrease in vital capacity, and if O_2 administration continues, ARDS. In the rare instances in which prolonged HBOT is indicated, the rate of development of pulmonary O_2 toxicity can be slowed by intermittent air-breathing periods (“air breaks”) (Fig. 75.13).

O_2 toxicity is related to the PO_2 of the inspired gas. At 1 ATA, 100% O_2 is as toxic as 16.7% O_2 at 6 ATA or 2% O_2 at 50 ATA. One method of quantification of O_2 exposure is the unit pulmonary toxic dose, or UPTD.[223] In this system, the number of UPTD units is calculated by the formula:

$$U = t \cdot \sqrt[m]{0.5/(P-0.5)}$$

where U is the unit; t is the exposure time in minutes; P is the inspired PO_2 in ATA; and m is a slope constant that has an empirical value of 1.2. After 1425 UPTD units of O_2 exposure, an average 10% decrease in vital capacity occurs. After 2190 UPTD units, an associated decrease of 20% occurs. Complete reversal of vital capacity decrements as large as 40% of control has been observed after extended O_2 exposure at 2 ATA.[223]

Reanalysis of a larger data set than the one used for the UPTD model, which included those data, resulted in a different prediction equation:

$$\%\Delta VC = -0.009 \cdot (P-0.38) \cdot t$$

where P and t are the same as for the previous equation (3).[224]

Using previously published data, Arieli and colleagues[225] developed the following equation:

$$\%\Delta VC = 0.0082 \cdot t^2 (PO_2/101.3)^{4.57}$$

where t is time in hours, and PO_2 is measured in kilopascals (kPa).

Although these algorithms may be useful as an approximate guide to safe O_2 exposures in populations, interindividual variability is such that they cannot be relied on to predict accurately the development of pulmonary O_2 toxicity for a specific patient.[226] Furthermore, O_2 toxicity can be modified by humidity,[227] circulating catecholamine and

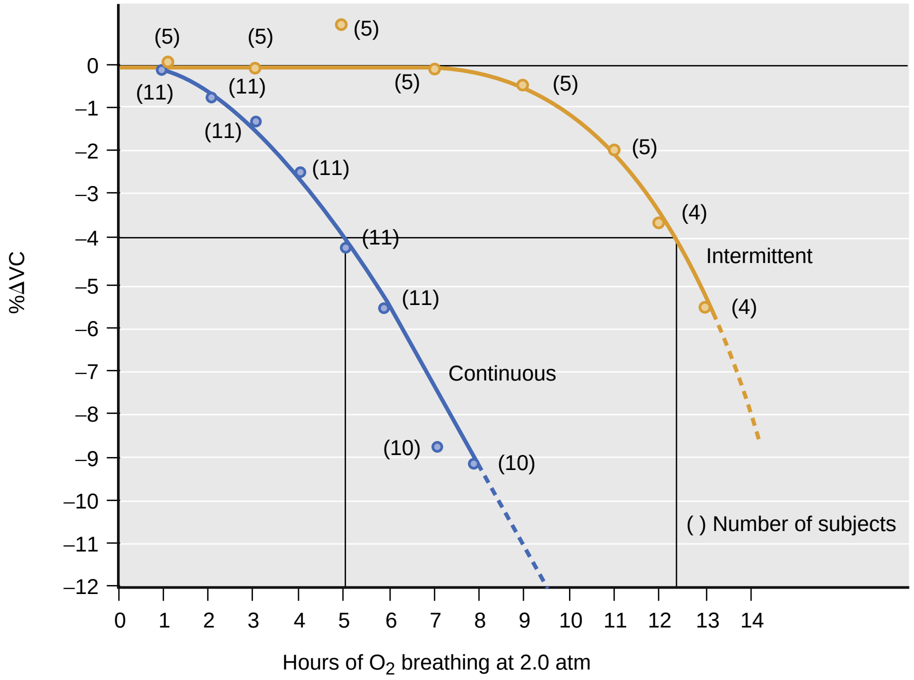

Fig. 75.13 Decrease in vital capacity *(VC)* as a function of time breathing 100% oxygen *(O_2)* at 2 ATA in humans. The figure illustrates the value of intermittent O_2 (20 minutes O_2, 5 minutes air) versus continuous O_2 administration in the prevention of pulmonary O_2 toxicity. The numbers in parentheses represent the number of subjects tested. (From Clark JM. Oxygen toxicity. In: Bennett PB, Elliott DH, eds. *The Physiology and Medicine of Diving.* Philadelphia, PA: WB Saunders; 1993:121–169. With permission.)

corticosteroid levels, leukocyte accumulation in the lungs (e.g., with pneumonia), and circulating endotoxin. A more useful guide to the development of pulmonary toxicity is the patient's symptoms, which include cough and inspiratory central burning chest pain. These symptoms do not occur during routine repetitive HBOT, but they may become evident during extensive O_2 periods at 2.8 ATA (e.g., when treating neurologic DCS). Asymptomatic persons usually have minimal or no change in vital capacity. Minor changes in forced expiratory volume in 1 second [FEV_1] reported during repetitive HBOT[228] are of uncertain clinical importance.

Some antineoplastic agents, such as bleomycin[229] and mitomycin C,[230,231] appear to predispose to fatal pulmonary O_2 toxicity (ARDS and respiratory failure) from what should otherwise have been well-tolerated doses of supplemental O_2. The risk of pulmonary O_2 toxicity from HBOT in patients with previous exposure to such agents is unknown, although we have treated several such individuals with a remote history of bleomycin treatment with repetitive doses of HBOT at 2 ATA for 2 hours (initially once daily, then increased to twice daily).[232] Occasional mild pulmonary O_2 toxicity symptoms such as retrosternal chest tightness did occur, but none of these patients experienced severe O_2 toxicity. Propensity to pulmonary O_2 toxicity engendered by these drugs appears to diminish a few weeks after their discontinuation.

CNS O_2 toxicity manifests as nausea, vomiting, numbness, twitching, dizziness, olfactory, acoustic, or gustatory sensations, and in its most severe form, as non-focal tonic-clonic seizures.[233,234] The probability of seizures increases with increasing PO_2 and time of exposure. In a study of 36 divers breathing 100% O_2 at 3.7 ATA, all experienced one or more of these symptoms within 100 minutes or less.[233,234] In clinical practice, convulsions in patients undergoing HBOT are rare at ambient PO_2 up to 2.5 ATA (typically 0.008% to 0.035% of treatments[235]), and they often have another predisposing factor (hypoglycemia). The probability of a convulsion is also greater when administered for acute indications such as CO poisoning.[236] Metabolic factors may reduce the seizure threshold, such as the administration of high-dose penicillin (e.g., for clostridial infection), sepsis, and hypoglycemia.

The treatment of hyperoxic seizures is immediate reduction of the inspired PO_2 until the seizure stops. Some physicians then routinely administer an anticonvulsant such as phenobarbital, phenytoin, or a benzodiazepine. It is recommended that the chamber should not be decompressed while the patient is actively convulsing because airway closure and failure to exhale during this period may cause pulmonary barotrauma. Hyperoxic seizures otherwise have no sequelae and rarely recur even if HBOT is continued. Thus, the occurrence of CNS O_2 toxicity should not preclude further HBOT. There is no evidence that hyperoxic seizures are more common in patients with preexisting seizure disorders.

An acute effect of HBOT on the eye is narrowing of the visual fields,[237] which is generally only observed at a PO_2 of 3 ATA or greater, and thus rarely, if ever, during routine HBOT. A subacute or chronic ocular effect is a change in the refractive index of the lens that results in myopia.[238,239] Such refractive index change occurs during the course of intermittent HBOT over several weeks and usually resolves in a similar period of time. However, some patients may be left with residual myopia, particularly older patients.[240]

Concern has been raised about the risk of retrolental fibroplasia in the unborn child of a woman who may require acute HBOT during pregnancy. Although many pregnant women have been treated with single exposures to HBOT (e.g., for CO poisoning), we are not aware of any subsequent occurrence of retrolental fibroplasia in the child. Pregnancy is not a contraindication to HBOT for appropriate acute indications (e.g., CO poisoning[163,165,167,241,242]), as the risk to the fetus of the underlying condition exceeds that of the treatment.

Inert Gas Uptake

Breathing air at high ambient pressure can result in nitrogen narcosis, a dose-dependent decrement in cerebral performance due to the anesthetic properties of nitrogen. This mostly occurs at ambient pressures exceeding 4 ATA, a treatment pressure that is used only for severe AGE or DCS. Nitrogen uptake can also theoretically result in DCS during or after decompression (see earlier). However, chamber decompression schedules are so conservative that this rarely occurs (most hyperbaric facilities use standard compressed air decompression tables such as those published by the US Navy).[221] Additional safety for the tender can be provided by 100% O_2 breathing for a period immediately before and during decompression. Rare episodes of DCS in hyperbaric tenders are usually of a minor nature, generally consisting of joint pain. Nitrogen narcosis and DCS could only occur in tenders in a multiplace hyperbaric chamber; patients breathe 100% O_2 and are therefore not susceptible.

Barotrauma

As the ambient pressure is altered, the pressure within gas-containing spaces in the body must equilibrate with the ambient pressure or undergo a change in volume. Volume change can easily occur in compliant compartments such as the gastrointestinal tract, but if the free flow of gas into and out of containing spaces surrounded by a rigid shell (e.g., the lung, paranasal sinuses, and middle ear) is obstructed, then tissue disruption and hemorrhage can occur. Indeed, the most common side effect of hyperbaric chamber use for patients is difficulty with middle ear pressure equilibration.[243,244] This causes pain, bleeding into the middle ear cavity ("squeeze"), and rarely, tympanic membrane rupture. Difficulty equilibrating middle ear pressure could also result in labyrinthine window (round or oval window) rupture, which has been reported in divers[245] but to the authors' knowledge not in patients undergoing HBOT. Patients who have previously had irradiation of the head and neck and acute respiratory tract infections are at particular risk. Squeeze may occasionally also affect the sinuses, resulting in acute pain. Despite the common occurrence of middle ear or sinus squeeze on compression, symptoms on decompression, as a result of the inability of gas to exit through the eustachian tubes or sinus ostia ("reverse squeeze"), are rare.

Pulmonary barotrauma is most likely during decompression. Areas of regional hypoventilation could lead to pulmonary over-pressurization and alveolar rupture, causing pneumothorax, pneumomediastinum, or AGE.[246,247] However, pulmonary barotrauma during HBOT is extremely rare, probably because of the slow decompression rates typically used. Although a pneumothorax should diminish in size and resorb more quickly after compression, continuing leakage of air from the lung could result in tension pneumothorax during decompression.[246]

Despite these potential adverse effects of HBOT, major complications are extremely rare.[248,249]

PRACTICAL ASPECTS OF HYPERBARIC THERAPY

Middle Ear Pressure Equilibration

In awake patients, equilibration may be accomplished using several techniques, such as performing intermittent Valsalva maneuvers, swallowing while the nose is pinched, thrusting the jaw forward, or simply by swallowing intermittently during compression. Equilibration may be facilitated by application of a topical nasal vasoconstrictor (e.g., oxymetazoline 0.05%) that shrinks the nasopharyngeal mucosa and increases the patency of the eustachian tube. For patients who cannot equalize despite these measures or for obtunded or intubated patients, myringotomy or tympanostomy tubes may be required.

Pulmonary Pressure Equilibration

Pneumothorax detected before HBOT is usually treated by insertion of a chest tube and water seal or Heimlich-type valve (in this instance, before monoplace chamber treatment, a chest tube should *always* be inserted). Caution must be exercised when using certain commercially available pleural suction regulators, which can exert high negative pleural pressures during chamber compression.[250] Such excessive suction can be relieved by an attendant inside a multiplace chamber by activating the manual pressure relief valve on the chest drainage unit. Patients with large bullous lesions in the lung are probably at increased risk of pulmonary barotrauma, and risk versus benefit of HBOT should be considered for such individuals before treatment.

Patient Monitoring

Despite the changes in the acoustic properties of compressed air, blood pressure measurement may be performed without difficulty with a standard sphygmomanometer and stethoscope. Aneroid pressure gauges are preferred to mercury to avoid contamination of the closed environment. Monitoring of the electrocardiogram (ECG) and of intravascular pressures requires that transducer cables be plumbed through the chamber wall to preamplifiers outside the chamber. Standard intensive care monitors can be used to provide simultaneous measurement of arterial and PA pressures and intermittent measurement of cardiac output by thermodilution. If pressure bags are used to drive continuous flow systems, they must be repressurized during compression and vented before or during decompression. Pulmonary artery catheter balloon ports should also be left open to the chamber during compression and decompression.

Defibrillation could generate a fire if sparking occurs or combustible materials are present in the vicinity of the paddles. Sparking and heat generation can be minimized by using a low-resistivity conductive gel between the electrodes and the skin[251] or preapplied conductive disposable pads.[252] To avoid pressure-related malfunction of the device, the defibrillator can remain outside the chamber and connected to the patient via through-hull high-voltage wiring. Despite the fear of causing fire, defibrillation has been carried out in multiplace chambers numerous times without arcing, fire, or explosion.[253,254] Defibrillation cannot be safely performed inside a monoplace chamber compressed with O_2.

Intravenous Fluid Administration

In multiplace chambers, the air volume within the drip chamber will shrink during the compression phase of the HBOT and expand during decompression (which could force air into the intravenous line). Most intravenous infusion pumps work well inside a hyperbaric chamber at pressure (although there are electrical safety issues—see later). Glass bottles are best excluded from the chamber because of the possibility of explosive rupture during decompression.

Administration of fluids to patients inside a pressurized monoplace chamber requires an infusion pump outside the chamber capable of handling the pressure differential (up to 3 ATA or 1500 mm Hg pressure gradient across the chamber wall). Check valves can prevent unintended backflow of blood from the patient in the event of disconnection of the pump. Rigid arterial pressure transducer tubing helps to prevent kinking while the patient is inside the chamber.

Blood Gas Assessment and Ventilator Management

Blood gas measurement on arterial samples obtained from a patient inside a hyperbaric chamber can be erroneous. There are two reasons. At 1 ATA, O_2 tensions that exceed the ambient pressure are supersaturated and thus O_2 will rapidly diffuse out of the blood, lowering its tension. An additional error (extrapolation error) results from the impossibility of accurate PO_2 electrode calibration at PO_2 values exceeding approximately 700 mm Hg. Blood gas tension measurement should therefore ideally be performed inside the hyperbaric chamber by using an appropriately calibrated analyzer. If such a capability is not available, rapid analysis at 1 ATA of decompressed samples can produce acceptably accurate values.[255]

Another approach is to estimate the hyperbaric PaO_2 based on measurements obtained at 1 ATA. Using a measured PaO_2 and a calculated alveolar PO_2 (P_AO_2) the ratio of the two (PaO_2/P_AO_2, or a/A ratio) is a constant.[104,105] On this basis, 1 ATA arterial blood gas values and the following equations can be used to predict PaO_2 at pressure.

The alveolar gas equation is required to calculate P_AO_2:

$$P_AO_2 = (Pb - P_{H_2O}) \cdot F_IO_2 - P_ACO_2 \cdot \left(F_IO_2 + \frac{1 - F_IO_2}{R} \right)$$

where Pb and PH_2O are, respectively, ambient and saturated water vapor pressures, and R is the respiratory exchange ratio. If $F_IO_2 = 0.2$, $R = 0.8$, and body temperature = 37°C, then this equation can be simplified to

$$PaO_2 = (Pb - 47) \cdot 0.2 - 1.2 \cdot PCO_2$$

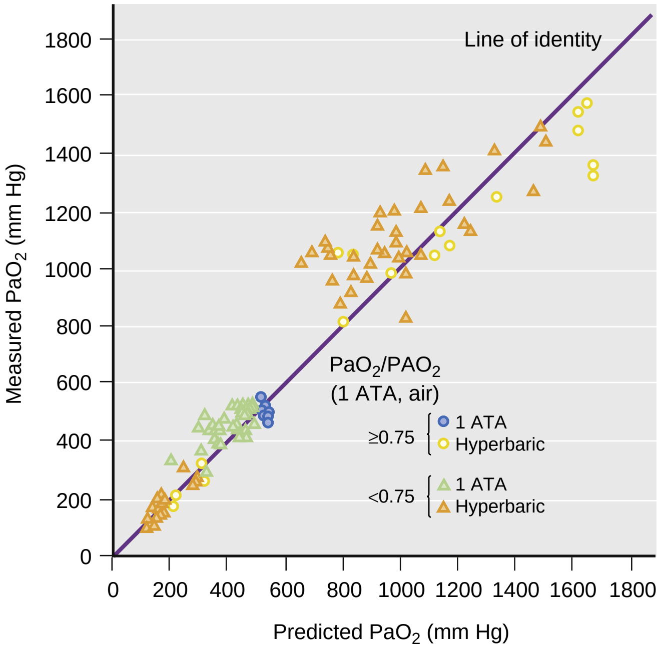

Fig. 75.14 Measured versus predicted arterial partial pressure of oxygen (PaO_2) at increased ambient pressure. Predicted PaO_2 is calculated from room air arterial blood gases, assuming that the arterial-alveolar PO_2 ratio (PaO_2/PAO_2, or a/A ratio) is a constant. Data are shown both for persons with normal lungs (a/A ratio ≥ 0.75) and for patients with gas exchange abnormalities (a/A ratio < 0.75). It is evident that PaO_2 predicted in this way is close to the actual measured PaO_2. (From Moon RE, Camporesi EM, Shelton DL. Prediction of arterial PO_2 during hyperbaric treatment. In: Bove AA, Bachrach AJ, Greenbaum LJ Jr., eds. *Underwater and Hyperbaric Physiology IX. Proceedings of the Ninth International Symposium on Underwater and Hyperbaric Physiology.* Bethesda, MD: Undersea and Hyperbaric Medical Society; 1987:1127–1131.)

Having calculated PAO_2 and measured PaO_2, the a/A ratio can then be obtained at 1 ATA. The predicted PaO_2 at increased ambient pressure while breathing 100% O_2 may then be obtained from this next equation:

$$PaO_{2\,(\mathrm{pred})} = \mathrm{a/A} \cdot [(760 \cdot \mathrm{ATA} - 47) - PaCO_2]$$

where ATA is the chamber pressure in atmospheres absolute. Although as yet there are no dose-response curves for HBOT, a reasonable aim is to achieve PaO_2 greater than or equal to 1000 mm Hg for routine chronic therapy and to as high a level as possible for treatment of acute necrotizing infections (Fig. 75.14).

A better monitor of tissue oxygenation may be mixed venous PO_2 ($P\bar{v}O_2$), which, in the absence of left-to-right shunt, may be a reasonably accurate estimate of mean tissue PO_2.[256] Thus, a low value may indicate inadequate tissue oxygenation despite HBOT, as a result of insufficiently high cardiac output.

Normal values for pH and PCO_2 under resting clinical hyperbaric conditions are the same as they are at 1 ATA.[106] PCO_2 (and hence pH) do not change significantly in blood samples that are decompressed.

Mechanical ventilation in a hyperbaric environment presents a variety of challenges. The ideal requirements for ventilation include small size, no electrical requirement, absence of flammable lubricants, ability to operate on a volume-cycled basis over a wide range of tidal volumes and respiratory rates, minimal modification requirement for installation, and ability to provide PEEP, as well as to ventilate in intermittent mandatory ventilation and assist/control modes.[257] Additionally, the ideal gas source to actuate the ventilator should minimize the risk of combustion caused by buildup of static electricity.

As ambient pressure increases, gas density is proportionately raised, whereas relatively little change occurs in gas viscosity. Therefore, in regions of turbulent flow (i.e., in the large airways) airway resistance increases. Measurements of respiratory conductance (the reciprocal of resistance) during tidal breathing[258] indicate that it varies with gas density according to the following formula:

$$G = G_0 \rho^{\kappa}$$

where G is lung conductance at gas density ρ, G_0 is the conductance at gas density 1.1 g/L (1 ATA), and κ is a constant that was found to have a mean value of −0.39. At 6 ATA, this equation predicts that lung conductance would decrease by 50%, which is equivalent to a doubling of pulmonary resistance. In addition, the higher gas density results in a less efficient distribution of ventilation, manifested by an increase in physiologic dead space.[259] The effects of these two phenomena include higher airway pressures during mechanical ventilation and an increased ventilatory requirement. If ventilator settings are not adjusted to compensate for the higher dead space, a rise in $PaCO_2$ will occur.

Several types of ventilators have been used and tested in hyperbaric chambers. Pressure-cycled devices have been used with some success because their compactness admirably fulfills the requirement for small size. However, continual adjustment of rate and cycling pressure is necessary with changes in ambient pressure. Volume-cycled ventilators seem to work well, although at increased pressure some changes in rate may occur.

Two specific safety considerations exist. First, in any ventilator delivering enriched O_2, a possible fire hazard can occur from O_2 buildup within the ventilator case or leakage of O_2 into the chamber. This hazard can often be offset by minor alterations (e.g., for a pneumatic ventilator, using air instead of O_2 to drive the bellows).[257] The risk of ignition can be substantially mitigated by purging the device with an inert gas such as 100% nitrogen (see later). Air-filled endotracheal tube cuffs tend to lose volume during compression and reexpand during decompression. Appropriate cuff inflation volume can be maintained either by manually adjusting the air pressure within the cuff during compression and decompression or filling the cuff with water.

Other Medical Devices

Some electrical devices (e.g., pacemakers, automated internal cardioverter-defibrillators, intravenous infusion pumps) have been specifically tested at high ambient pressures; specific information can usually be obtained from the manufacturers. Ventricular assist devices may work satisfactorily, however the required rechargeable batteries (typically lithium) may be unsafe. To the authors' knowledge, at this time ECMO devices have not been tested or used during hyperbaric oxygen therapy.

Atmosphere Control

Chamber atmosphere safety includes management of levels of O_2, CO_2, and trace gases. In a multiplace chamber it is essential that the patient breathe as high a concentration of O_2 as possible (usually 98% or greater) while maintaining the chamber O_2 concentration close to 21% in order to minimize fire hazard. In some hyperbaric units, head tent O_2 concentration is routinely monitored. In others, the concentration is assumed to be high because of a high rate of O_2 flow through the head tent. Leakage of O_2 from head tents, masks, and ventilators tends to raise the chamber O_2 concentration. Typically, an upper limit of approximately 23% is used as a criterion for ventilating the chamber with air or small volumes of 100% nitrogen until the O_2 concentration decreases.

Significant elevations of inspired CO_2 concentration cause cerebral vasodilatation, increased cerebral blood flow and tissue PO_2, thus increasing the risk of CNS O_2 toxicity. Therefore, a typical standard for the upper limit for head tent CO_2 is 1% "surface equivalent" CO_2, equal to a partial pressure of 7.6 mm Hg. Using a nonscrubbing (open circuit) system, head tent O_2 flow rates of 40 to 60 L/min (measured at chamber pressure) are usually adequate to keep CO_2 levels at such a level. Chamber CO_2 is usually limited to less than 0.5% "surface equivalent" (3.8 mm Hg).

Trace gases that may enter the environment include CO and hydrocarbons from improperly functioning compressors or from automobile exhaust that may be near the compressor air intake. Volatile gases such as alcohol vapor from skin disinfectant solutions and mercury vapor from spillage of sphygmomanometer columns may also pollute the atmosphere. Trace gas concentrations that are innocuous at atmospheric pressure can be toxic under hyperbaric conditions because their pharmacologic or toxic effects are related to partial pressure. Mercury in any form should be excluded from hyperbaric chambers because spillage can cause acute toxicity in chamber occupants.

Considerations of battery use may have implications for chamber atmosphere control as well as fire hazards. All batteries release small quantities of hydrogen, although not usually in amounts that would be hazardous. Lithium-sulfur dioxide batteries carry a theoretic risk of sulfur dioxide discharge. Similarly, an objection exists to the use of mercury cells (now banned in the United States). Alkaline cells are considered safe, although temporary failure has been observed at extremely high ambient pressures (40-60 ATA).

Fire Hazards

Although fires in hyperbaric chambers are rare, they are usually lethal. The effects of fire at elevated ambient pressure are so devastating and so fast that fire extinguisher systems may not be effective.[260] The very real risk of fire in hyperbaric chambers has been illustrated by recent accidents in which chamber fires were started by a hand warmer, a sparking toy, and other sources of ignition carried into the chamber in the patient's clothing. Minimization of these risks involves the following:

Controlling chamber O_2 concentrations (irrelevant in a monoplace chamber)
Minimizing the use of combustible materials within the chamber
Eliminating sources of heat and spark
Having a chamber fire-extinguisher system

The geometric increase in burning rate with increases in O_2 concentrations mandates careful monitoring of chamber O_2, as already noted. At increased ambient pressure, burning occurs more rapidly, even when O_2 concentration is 21%. Cotton garments are recommended because of their reduced risk of static electricity. Elimination of hair grease and humidification of the O_2 within the head tent can reduce the risk of hair ignition. Hydrocarbon lubricants (e.g., for stretcher wheels) can spontaneously ignite on contact with aluminum in the presence of high O_2 tensions and should therefore be replaced with nonflammable fluorocarbon lubricants.

Sources of sparks from electrically powered equipment should be minimized. Cigarette lighters, matches, and other sources of ignition should be excluded from the chamber. Plugging and unplugging electrical cables during hyperbaric treatments is a source of sparking that can be eliminated by taping all electrical plugs onto receptacles before compression. In multiplace chambers, the flammability of electrically powered devices (e.g., intravenous controllers) can be reduced by purging with 100% nitrogen through ports drilled in the covering, at a rate sufficient to keep O_2 concentration at a level that does not support combustion (typically at a flow rate of two to three times the internal volume per minute). Electrical systems used in monoplace chambers must comply with specific codes, which stipulate the types of switches, grounding, and insulation that can be used.[219]

Volatile anesthetics can be combustible at 1 ATA in high concentrations. However, isoflurane and sevoflurane Dräger vaporizers have been tested up to 3 ATA using 100% O_2, with no evidence of spontaneous combustion at room temperature. Given the experience with halothane under hyperbaric conditions,[261] without any reported fires, and the resistance to combustion in 100% O_2 at 1 ATA, in the absence of a source of ignition it is unlikely that any of the modern fluorinated anesthetics pose a fire safety hazard in the hyperbaric environment.

Evaluation of a Patient for Safety of Hyperbaric Oxygen Treatment

In addition to ensuring that HBOT is indicated for the disease process in question, it is important to assess the patient in terms of general effectiveness and safety of HBOT. The following issues are pertinent:

Whether a sufficient elevation in PaO_2 can be obtained
Whether the patient can equilibrate middle ear pressure
Optimization of reversible obstructive lung disease and the presence of pulmonary bullae or blebs
Whether the patient is susceptible to claustrophobia

The calculation of predicted PaO_2 in the hyperbaric chamber was described previously. For example, a patient who has sufficient lung disease or injury such that PaO_2 during treatment would not exceed 1000 mm Hg would probably obtain marginal benefit from HBOT unless the reason for HBOT is gas bubble disease.

The ability to vent the middle ears may be assessed before treatment by observing directly the tympanic membrane with an otoscope while the patient holds his or her nose or performs a Valsalva maneuver. Movement of the eardrums indicates a patent eustachian tube and the ability to equilibrate middle ear pressure. If otic barotrauma is difficult to avoid (e.g., with mental obtundation or the presence of an endotracheal tube) or because of a condition that may render the patient susceptible to inner ear injury (e.g., stapedectomy), myringotomy or tube placement can be performed prior to HBOT. The presence of pulmonary bullae or blebs represents a relative contraindication to HBOT because of the possibility of barotrauma, although a large clinical experience suggests that the risk is extremely low.

For patients requiring more than 20 to 30 HBOT sessions, periodic checks of visual acuity may be useful to detect hyperbaric myopia.

Because most hyperbaric chamber systems are small and cramped, patients who cannot tolerate enclosed spaces may require anxiolytic therapy to facilitate toleration of the HBOT.

Delivery of Anesthesia at Increased Ambient Pressure

A review of the problems of anesthesia under HBOT was published as a report to a committee of the American Society of Anesthesiologists.[262] This report explored various issues, including the potential for nitrous oxide to be used as a sole anesthetic.

Anesthesia while breathing spontaneously in a 100% O_2 atmosphere at 3 ATA was reported in the 1950s for radiation therapy.[263] Patients were intubated after administration of pentobarbital 250 to 750 mg and meperidine 100 mg; some patients also received chlorpromazine 50 mg. Intubation was performed after succinylcholine and topical anesthesia of the airway. Patients breathed spontaneously.

Anesthesia may be required during the hyperbaric exposure. Ross and associates[264] discussed the challenges of anesthesia up to 35 ATA, to provide care for injured divers while in a saturation diving system (e.g., in North Sea oil fields). These investigators suggested using intravenous instead of inhaled general anesthesia because of the problems of pollution of the chamber environment. Regional anesthesia was recommended whenever possible. The authors noted that muscle relaxants should be titrated to effect because some degree of pressure reversal at around 10 ATA has been reported.

Since the 1960s anesthesia has been performed at increased ambient pressure using a variety of agents for carotid endarterectomy,[265] cesarean section,[266] therapeutic lung lavage for patients with alveolar proteinosis (Fig. 75.15),[209,210] emergency surgery in a saturation dive,[267] open heart surgery,[268] and enhancement of the effectiveness of irradiation of carcinoma.[269]

Inhaled Anesthesia. Inhaled anesthesia of any type can pollute the enclosed chamber atmosphere with anesthetic gases, which may exert pharmacologic effects on medical personnel inside the chamber, particularly at high ambient pressures. Russell and associates[270] reported nitrous oxide concentrations in chamber air of 2500 ppm; ventilation of the chamber with air at a high rate (3500 L/min of air) was required to reduce the concentration to 25 to 75 ppm.

NITROUS OXIDE. The increased ambient pressure in a hyperbaric chamber allows nitrous oxide to be used at partial pressures exceeding its MAC.[270-272] Although in both studies induction of anesthesia by nitrous oxide was rapid (<60 seconds), it was accompanied by tachypnea, tachycardia, hypertension, diaphoresis, muscle rigidity, catatonic jerking of the extremities, eye opening, and opisthotonus. After 2 to 4 hours of anesthesia, most subjects emerged rapidly from the anesthetic; however, the majority subsequently experienced nausea and vomiting, which was often severe.

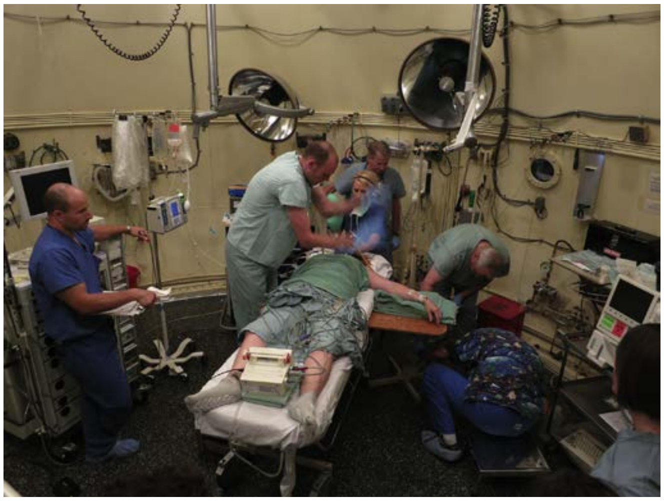

Fig. 75.15 General anesthesia administered in a multiplace hyperbaric chamber for support of arterial oxygenation during therapeutic lung lavage. Lung lavage is performed by flooding one lung with normal saline via a double-lumen endotracheal tube. Protein washout is performed by cyclic filling and emptying with 400 L to 500 mL saline volumes until the effluent clears.[341] After a period of 60 minutes the contralateral lung is lavaged using the same technique. Depicted is a patient under general anesthesia with propofol/opioid receiving manual chest percussion during the emptying phase. (From Duke University Medical Center.)

A potential problem associated with nitrous oxide anesthesia at high ambient pressures is the possibility that tissues could become supersaturated during decompression, thus allowing nitrous oxide bubbles to form during decompression. This complication was not observed by Russell and associates,[270] who used an empiric staged decompression schedule with a decompression stop for 30 minutes at 1.3 ATA while the patients breathed 100% O_2. Bubble formation can occur without decompression if the patient breathes one gas while surrounded by an atmosphere of another gas that is more diffusible. For example, breathing air while in a helium-O_2 environment at 5 to 7 ATA can lead to urticaria and vestibular dysfunction.[273] The reason is rapid diffusion of helium into tissues that causes local inert gas pressure to exceed ambient pressure (isobaric gas counterdiffusion). This phenomenon can occur even at normal atmospheric pressure if a person breathes nitrous oxide-O_2 while surrounded by helium.[274] Therefore, it is imperative that nitrous oxide never be administered in a helium-O_2 atmosphere.

Another risk of hyperbaric nitrous oxide is the dilutional effect of large volumes of dissolved gas entering the lungs during decompression, causing dilutional hypoxia. This situation can be prevented by administration of an O_2-enriched breathing mix for several minutes before decompression.

In patients who have recently engaged in scuba diving or have suffered DCS, nitrous oxide should be avoided, even

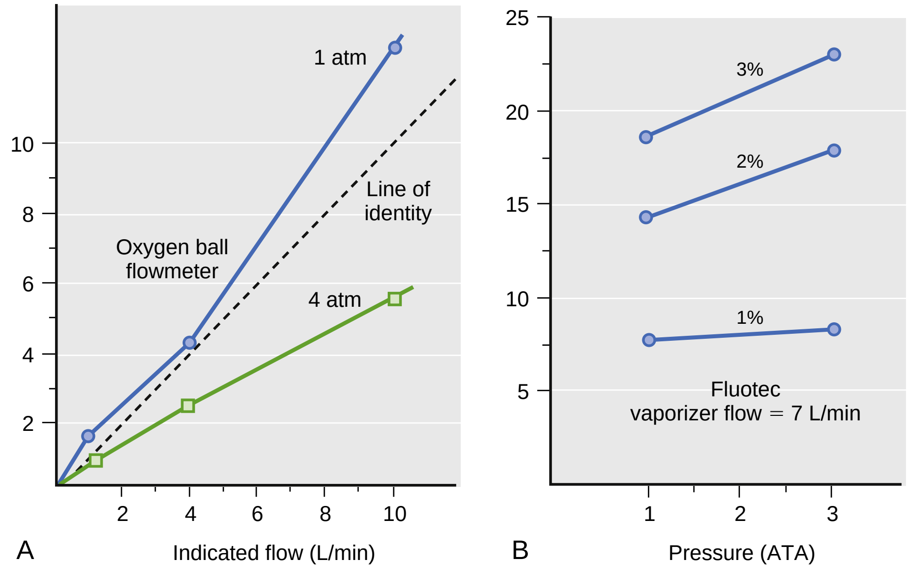

Fig. 75.16 Performance of an anesthetic vaporizer system at increased ambient pressure. (A) Flow characteristics of a rotameter system are shown. At 4 ATA, the actual delivered flow is less than 60% of the flow indicated by the rotameter. (B) Fluotec vaporizer output in partial pressure of halothane as a function of ambient pressure. Only small increases in delivered partial pressure are evident at 3 ATA, at the 2% and 3% settings. (From Committee on Hyperbaric Oxygenation. *Fundamentals of Hyperbaric Medicine. Publication No. 1298*. Washington, DC: National Academy Press; 1966.). *ATA,* Atmospheres absolute.

at 1 ATA, because its administration may result in tissue or blood bubble growth and recrudescence of pain or neurologic symptoms. Neurologic symptoms can occur after nitrous oxide anesthesia and apparent spontaneous resolution of DCS.[275]

HALOGENATED ANESTHETICS. The effect of a volatile anesthetic on a patient is proportional not to the alveolar concentration but to the partial pressure of the anesthetic. For example, the effect of 1% halothane at 1 ATA (with a partial pressure of 7.6 mm Hg) is equivalent to a 0.5% concentration at 2 ATA (with the same partial pressure). The anesthetic concentration of an anesthetic-specific calibrated vaporizer varies with ambient pressure, but in a manner such that delivered partial pressure remains constant (see Fig. 75.12). Because of the effect of increased gas density on this flow ratio, in practice the delivered partial pressure depends somewhat on ambient pressure. A slightly increased partial pressure of halothane delivered by a Fluotec vaporizer at 3 ATA has been observed (Fig. 75.16).[262] Our testing of a sevoflurane vaporizer revealed delivery of a constant partial pressure of anesthetic up to the maximum tested ambient pressure: 3 ATA.

Rotameter flowmeters calibrated at 1 ATA will indicate falsely high values at increased ambient pressure because of the increased gas density. McDowell[276] reported the following relationship for rotameter flow:

$$\mathrm{Flow}_{\mathrm{actual}} = \mathrm{Flow}_{\mathrm{read}} \cdot \sqrt{\frac{\rho_1}{\rho_P}}$$

where $\mathrm{Flow}_{\mathrm{actual}}$ and $\mathrm{Flow}_{\mathrm{read}}$ are the actual and scale reading flows, and ρ_1 and ρ_P are the gas densities at 1 ATA and P ATA, respectively. This inaccuracy in rotameter performance up to 4 ATA has been confirmed by others (see Fig. 75.16).[262]

Intravenous Anesthesia. Intravenous anesthetics behave similarly and are unlikely to be affected within the usual clinical range of ambient pressure (see Chapter 23). There is no evident alteration in the pharmacokinetics of either meperidine[130] or pentobarbital[131] at ambient pressures up to 6 ATA. For therapeutic lung lavage, we have provided general anesthesia at ambient pressures up to 3 ATA by using conventional doses of ketamine and benzodiazepines or propofol and narcotics with nondepolarizing muscle relaxants.

Regional Anesthesia. Regional anesthesia is likely to be both safe and effective in a hyperbaric environment by avoiding the requirement for mechanical ventilation. A bowel resection was performed at an ambient pressure of 6.75 ATA in a helium-O_2 environment by using local injection of lidocaine supplemented with parenteral meperidine.[267] Extreme care should be taken to ensure sterile technique because of the propensity for enhanced bacterial growth in the warm, humidified environment of a hyperbaric chamber, particularly during saturation chamber exposures.

FUTURE DIRECTIONS IN HYPERBARIC OXYGEN THERAPY

Preoperative Hyperbaric Oxygenation

Preconditioning is described as the application of an insult to activate endogenous protective mechanisms to lessen the morphologic and functional sequelae of a subsequent insult. Ischemic preconditioning is the application of a brief period of ischemia, which activates endogenous protective mechanisms to reduce the damage from subsequent ischemic insults. Ischemic preconditioning was first described in canine myocardium and subsequently was shown to also exist in the brain. Since then, intense research in the field of pharmacology has ensued to identify other agents that lead to preconditioning, such as volatile anesthetic agents, lipopolysaccharide exposure, heat, CNS seizures, hypoxia, and hyperoxia, and more recently hyperbaric hyperoxia.[277]

Several clinical trials have provided evidence that HBOT before cardiac or surgical procedures can improve outcome. Sharifi and associates described the use of HBOT to inhibit restenosis after percutaneous coronary intervention in acute myocardial infarction.[278] In 2005, Alex and associates observed that repetitive pretreatment with three sessions of HBOT at 2.4 ATA before on-pump coronary artery bypass graft (CABG) surgery reduced neuropsychometric dysfunction and modulated favorably the inflammatory response after cardiopulmonary bypass.[279] Yogaratnam and associates reported that preconditioning with a single session of HBOT at 2.5 ATA before on-pump CABG surgery improved left ventricular stroke work post-CABG surgery while reducing intraoperative blood loss, ICU length of stay, and postoperative complications.[280] Li and associates demonstrated in patients undergoing on-pump and off-pump CABG that HBOT preconditioning decreased the release of cerebral and myocardial biochemical markers. Patients in the on-pump group pretreated with hyperbaric oxygen had a reduced length of ICU stay and decreased use of inotropic drugs.[281]

The mechanism by which HBOT can be protective is not currently known but does not involve support of metabolism by increased tissue oxygen stores, since tissue and blood oxygenation are dissipated within minutes after hyperbaric exposure. The etiology of cerebral injuries is probably multifactorial, including cerebral microemboli, global cerebral hypoperfusion, inflammation, cerebral temperature modulation, and genetic susceptibility.[277,282] The mechanism of protection therefore may include HBOT-induced oxidative stress due to increased reactive oxygen species (ROS) generation, which could induce ischemic tolerance similar to ischemia-reperfusion. Alternatively, HBOT preconditioning may reduce ischemia-reperfusion damage by reducing tissue leucocyte recruitment and activation, reduction of tissue edema, protection from cellular necrosis, reduction of tissue apoptosis, and improving tissue outcome and preservation.[283-285] Another possible mechanism is upregulation of antioxidant enzymes such as superoxide dismutase,[286] and possibly also heme oxygenase-1, as shown in a model of liver ischemia.[287]

Published data are highly suggestive of a beneficial effect of HBOT when administered before or after selected procedures.[277,288] The role of HBOT in this setting will be determined by larger clinical trials.

Stroke

Several studies of middle cerebral artery occlusion in rats have demonstrated beneficial effects of hyperbaric oxygen.[289-293] In an unselected case series of patients with acute stroke treated within 5 hours of symptom onset, some patients improved with HBOT where arterial PO_2 was 1100 to 1300 mm Hg.[294] Since then there have been several clinical studies, with mixed results,[295] perhaps because of the failure to start HBOT in a timely fashion[296] or use of subtherapeutic PO_2. Interestingly, a recent double blind study reported improved outcome when HBOT was administered after the acute stroke, suggesting some effect on neuroplasticity.[297]

Acute Traumatic Brain Injury

Hyperoxia may have several protective mechanisms of action in severe traumatic brain injury (TBI), including improved oxidative metabolism and mitochondrial function, and reductions in intracranial hypertension, apoptosis, neuroinflammation, and free radical mediated damage. Support for efficacy of HBOT is provided by small clinical trials and mechanistic observations.[298-301] This has led to an NIH-supported multi-center trial of HBOT in acute TBI (Hyperbaric Oxygen Brain Injury Treatment Trial [HOBIT], ClinicalTrials.gov Identifier: NCT02407028).

Summary

Environmental exposures can cause specific types of clinical conditions that require targeted therapy. Experience with compressed air and diving has led to new treatments using hyperbaric oxygen. Increasingly widespread use of HBOT to treat critically ill patients has created a demand for individuals skilled in using this technology. Planning and design of monitoring capabilities will enable optimal control of hemodynamics and oxygenation. Patient safety in this environment can be achieved with careful attention to detail that includes patient selection and monitoring, and chamber procedures. Optimized treatment schedules will evolve from studies of mechanism of action and further clinical trials. Advances in prevention and treatment of O_2 toxicity may allow more prolonged therapy than can currently be safely administered, and a more aggressive approach to ischemic and infectious syndromes.

76 Regional Anesthesia in Children

SANTHANAM SURESH and PER-ANNE LONNQVIST

KEY POINTS

- Over the last three decades, regional anesthesia in pediatrics has become an integral part of everyday practice.
- Regional anesthesia appears as a viable option for treating intraoperative and postoperative pain control in children.
- In recent years, there has been an upsurge in the use of peripheral nerve blockade in infants and children.
- Large pediatric databases have contributed pertinent data on the safety of peripheral nerve blockades.
- Peripheral catheter techniques are becoming routine practice with data substantiating their use in pediatric patients.
- The efficiency and safety of these techniques may facilitate early ambulation with improved pain management and includes treatment at home and improved rehabilitation of children.
- Landmark techniques and nerve stimulation localization, which were commonly used for regional anesthesia in children, are being replaced by ultrasound guidance.
- The benefits of the ultrasound-guided regional technique are visualization of targeted nerves and spaces, the spread of injected local anesthetic, and improved safety of the blocks.
- The use of ultrasound guidance for performing peripheral nerve blocks permits the decrease of local anesthetic doses, decrease in number of punctures, and increase in the onset time and duration of sensitive block.
- To avoid local or systemic toxicity, the dose of local anesthetic, in terms of volume and concentration, should be carefully calculated. The introduction of lipid rescue has decreased the incidence of serious complications associated with the use of regional anesthesia.

Introduction

Pediatric regional anesthesia and the research into techniques and applications have followed its use in adults. The adaptation of the pediatric practitioners to several well-described blocks and their use in children have clearly allowed us to explore opportunities for adapting the use of these blocks in even low birth weight neonates. Emerging data from both Europe and North America support the universal acceptance and utilization of regional anesthesia in infants and children. In addition, the introduction of Enhanced Recovery After Surgery (ERAS) protocols in children is now gaining acceptance as standardized methods for the delivery of postoperative analgesia.

The use of ultrasound guidance for regional anesthesia has opened several avenues for regional anesthesia techniques. In addition, a recent Cochrane Review demonstrated the effectiveness of ultrasound guidance as well as the opportunity to reduce the local anesthetic dosage for regional techniques (see ref. [1] below).

Relevant Differences Between Children and Adults

ANATOMIC DIFFERENCES

Change in Body Size Resulting From the Growth Process

The most obvious difference between children and adults is body size. "Normal" full-term neonates weigh 3 to 3.5 kg, with a height of 50 cm, and within 10 to 15 years they will multiply their weight by more than 12 (>1200%) and their height by more than 3 (>300%). During the early stages of development the spinal cord occupies the spinal canal entirely, but later the growth of vertebrae exceeds that of the cord,[1a] and the last spinal nerves, the cord, and its envelopes are contained within the spinal canal. At birth the dura mater ends at the level of the third or fourth sacral vertebra and the cord (conus medullaris) at the L3 or L4 level. It is only at the end of the first year of life that the adult level is attained—that is, L1 for the conus medullaris and S2 for the dural sac.

Anatomic relationships and landmarks are constantly changing with growth throughout infancy and childhood, which interferes with regional procedures and requires a working knowledge of the developmental anatomy and the assistance of accurate techniques for localization of anatomic spaces and nerve trunks.

Congenital malformations, genetic disorders, and consequences of fetal and neonatal asphyxia (cerebral palsy) are observed in the pediatric population resulting in surgical procedures that are done to facilitate mobility or adaptation to normal childhood life.

The main pediatric anatomic and physiologic factors that can influence indications for performance of regional block procedures are listed in Table 76.1.

Delayed Ossification of Bones and Fusion of Sacral Vertebrae

Bones of neonates, including vertebrae, are mostly cartilaginous. Sharp needles can easily traverse them because cartilage offers little resistance to penetration, and ossification nuclei can be severely damaged, thus compromising further bone and joint development. Consequently, bone contact should be avoided as often as possible during block procedures, especially in infants. This cartilaginous structure also allows easy penetration of radiographs and ultrasound.

Development of Curvature of the Spine

At birth, a single spinal curvature is present and the orientation of epidural needles is the same regardless of the intervertebral space. Flexures, however, are not fixed, and they can be easily counteracted by forced flexion almost throughout childhood because of persistent spinal flexibility, which is a major advantage in the pediatric period (in addition to the absence of osteophytes).

Loose Attachment of Fasciae and Fluidity of Epidural Fat

Fasciae and perineurovascular sheaths are loosely attached to underlying structures (e.g., nerves, muscles, tendons, vessels). This allows extended spread of local anesthetics, resulting in high-quality nerve blockade regardless of the technique but also, occasionally, undesirable spread to distant nerves or anatomic spaces. The epidural fat is very fluid in infants and young children (up to 6-7 years of age). This fluidity combined with the loose attachment of the sheaths surrounding the spinal roots favors consistent leakage of local anesthetics injected within the epidural space; therefore comparatively large volumes of epidural local anesthetics (up to 1.25 mL/kg) are required to reach desired levels of anesthesia.

Delayed Myelinization of Nerve Fibers

Myelinization begins during the fetal period in cervical neuromeres and extends cephalad and caudad,[2,3] but the process is not finalized before the twelfth year of life. Myelinization is especially poor in infants; the lack of fully developed nerve fibers is the main reason why they are unable to walk. A major pharmacologic consequence of this condition is that local anesthetics can penetrate and block nerve fibers more easily. Diluted solutions of local anesthetics provide the same quality of nerve blockade as with at least twofold more concentrated solutions in adults. Onset time is shortened, but duration of blockade is reduced because trapping of local anesthetics within myelin with subsequent progressive release is reduced and because local circulation and therefore vascular absorption are greater in infants.

PAIN PERCEPTION

Somatic pain is a subjective sensory experience resulting from the intermixing of three main components[4]: motivational-directive, sensory-discriminatory, and cognitive-evaluative. The motivational-directive component is conveyed by unmyelinated C fibers (“slow” pain or “true” pain). Pain leads to protective reflexes such as autonomic reactions, muscle contraction, and rigidity. C fibers are fully functional from early fetal life onward. Connections between C fibers and dorsal horn neurons are not mature before the second week of postnatal life. However, nociceptive stimulations transmitted to the dorsal horn by C fibers elicit long-lasting responses,[5,6] probably as a result of extensive depolarization of surrounding neurons in response to the production of large amounts of substance P. As the number of dorsal horn receptors to substance P decreases during the first 2 weeks of life, this exaggerated response of neonates to nociceptive stimulation progressively disappears. The inhibitory control pathways, which are immature at birth, develop concomitantly.

Painful procedures during the neonatal period modify subsequent pain responses in infancy and childhood,[7] depending on the developmental stage of the infant (full-term vs. preterm) and the infant’s cumulative experience with pain. Noxious procedures in full-term neonates react with heightened behavioral responsiveness, whereas preterm neonates react with a dampened response. When analgesic drugs (local anesthetics or opioids) are administered before painful procedures, infants demonstrate less evidence of procedural pain and a reduction in the magnitude of long-term changes in pain behaviors.[7]

A major difficulty in assessment, and, at times, even identification of pain in children pertains to the inability of young patients to communicate with their caregiver and precisely express their distress and discomfort. During the past 2 decades, pediatric pain has received considerable attention, and reliable age-related pain scales have been developed to evaluate both the severity of pain and the efficacy of its treatment.

PHARMACOLOGY OF LOCAL ANESTHETICS AND ADDITIVES

Two main factors influence pharmacologic properties of medications in children: (1) immaturity of some enzyme pathways and their replacement by other biochemical pathways and (2) progressive increase in body surface area concomitantly with the growth process. Drug prescriptions made according to body surface area are the same as (or in simple ratio with) adult dosing.[8] However, body surface area is not easily obtained and, in practice, doses are calculated according to body weight and require constant adaptation as the child grows up; dosage errors are not infrequent.

TABLE 76.1 Main Anatomic and Physiologic Factors in the Pediatric Period That Can Influence the Selection or Performance of a Regional Block Procedure

Pediatric Factors (Mainly Infants)	Resulting Danger	Implications for Regional Anesthesia
Lower termination of spinal cord	Increased risk for direct trauma to the spinal cord	Avoid epidural approaches above L3 whenever possible.
Lower projection of dural sac	Increased risk for inadvertent penetration of the dura mater	Check for cerebrospinal fluid reflux, including during caudal approaches. Favor low approaches to the epidural space.
Delayed myelinization of nerve fibers	Easier intraneural penetration of local anesthetics	Onset time is shortened, and diluted local anesthetic is as effective as more concentrated anesthetic in adults.
Cartilaginous structure of bones and vertebrae	Reduced resistance to penetration by sharp needles Danger of direct trauma and bacterial contamination of ossification nuclei compromising further bone or joint growth	Avoid use of thin and sharp needles; use short and short beveled ones instead. Do not apply excessive force on needle: if resistance is felt, stop trying to insert the needle farther.
Lack of fusion of sacral vertebrae	Persistence of sacral intervertebral spaces	Intervertebral sacral epidural approaches can be performed throughout childhood.
Delayed development of curvatures of the spine	Cervical lordosis (3-6 months) Lumbar lordosis (8-9 months)	Same orientation of epidural needles is appropriate whatever the spinal level before 6 months of age; then adapt needle orientation to spinal flexures.
Changing axis of coccyx and absence of growth of sacral hiatus	Sacral hiatus comparatively smaller with increasing age	Identification of sacral hiatus becomes more difficult after 6-8 years (increased failure rate of caudal anesthesia).
Delayed ossification and growth of iliac crests	Tuffier line, which joins anterior superior iliac spinous processes, crosses the spine at L5 or lower in infants.	This line passes over L5-S1 interspace instead of L4-L5 interspace.
Increased fluidity of epidural fat	Increased diffusion of local anesthetic up to 6-7 years of age	Excellent blockade after caudal anesthesia can be achieved up to 6-7 years of age.
Loose attachment of sheaths and aponeuroses to underlying structures	Increased spread along nerve paths with danger of penetrating remote anatomic spaces and blocking distant nerves	Larger volume of local anesthetic is required for epidural blocks because of leakage along spinal nerve roots. Smaller volume of local anesthetic is necessary to produce excellent peripheral blocks.
Enzymatic immaturity	Slower metabolism of local anesthetics (usually compensated by other enzyme pathways)	Increased mean body residency time and half-life, with accumulation (especially after repeat injection and continuous infusions of local anesthetic), are characteristic.
Increased extracellular fluids	Increased distribution volume and mean body residency time of local anesthetic (and most medications)	Decreased C_{max} occurs after single injection but accumulation occurs with repeat or continuous injections.
Low plasma protein content (HSA and AGP)	Competition at nonspecific HSA binding sites Limited capacity of specific binding of local anesthetic by AGP, resulting in increased plasma concentration of the free fraction	Increased unbound free fraction of all local anesthetic occurs, with greater danger of systemic toxicity
Increased cardiac output and heart rate	Increased regional blood flow resulting in increased systemic absorption of local anesthetic	Increased systemic absorption of local anesthetic occurs (decreased T_{max} and shorter duration of blockade). Increased efficacy of epinephrine. Vasoconstriction reduces absorption (thus toxicity) and prolongs duration of blockade.
Sympathetic immaturity, diminished autonomic adaptability of the heart, smaller vascular bed in lower extremities	Hemodynamic stability during neuraxial blocks	Fluid preloading and use of vasoactive agents are unnecessary.
Delayed acquisition of body scheme and conceptualization, anxiety	Inability of patients to locate precise body areas Concept of paresthesia not understandable Difficult cooperation	Nerve and space identification requires application of location techniques independent of patient's cooperation. Heavy sedation or general anesthesia is required in most patients (especially when a "dangerous" technique is planned to avoid detrimental consequences of panic attacks at a critical phase of the block procedure).

AGP, α_1-Acid glycoprotein; *C_{max},* peak plasma concentration; *HSA,* human serum albumin; *T_{max},* time to reach C_{max}.

Local Anesthetics

Chemical properties and mechanisms of action of local anesthetics are detailed elsewhere in this book (see also Chapter 29); they are basically the same during the pediatric period and only pharmacokinetic properties may notably differ, especially in neonates and infants.[9]

Local Fixation

Schematically, local anesthetic fixation is reduced and spread is increased in infants in contrast to the occurrence in adults, especially within the epidural space, because the epidural fat is more fluid and less densely packed. The main consequences are (1) shorter onset time of action, (2) more extended longitudinal and circumferential spread of local anesthetics, and (3) shorter duration of action because of reduced secondary release from local binding sites.

Regional Spread Toward the Target. The target of local anesthetic action is voltage-dependent sodium channels located within nerve fibers. Nonionized molecules can achieve penetration of only biologic membranes, and the speed of the process depends on the number and thickness (increasing with age) of sheaths.

Systemic Absorption and Distribution

PLASMA PROTEIN BINDING. Nonionized local anesthetics easily traverse the capillary wall close to the injection site. Because cardiac output and local blood flow are two to three times greater in infants than in adults, systemic local anesthetic absorption is increased accordingly and vasoactive agents such as epinephrine are very effective in slowing systemic uptake.

Once they have penetrated within the vascular bed, local anesthetics undergo plasma protein binding mainly to human serum albumin (HSA) and α_1-acid glycoprotein (AGP), or orosomucoid. HSA has a low affinity for local anesthetics, and many pharmacologic agents can compete at available binding sites. Furthermore, plasma levels of HSA are low during the first months of life, especially in premature and fasted infants; thus the protection offered by HSA against systemic toxicity of local anesthetics is low and decreases postoperatively. The affinity of AGP for local anesthetics is 5000 to 10,000 times greater than that of HSA, which makes AGP very effective to protect the patient from systemic toxicity (which depends on the unbound free form of local anesthetics). However, plasma concentration of AGP is very low at birth (0.2-0.3 g/L) and does not reach adult levels (0.7-1.0 g/L) before 1 year of age.[10-12]

Because plasma concentration of the two proteins able to bind local anesthetics are low at birth, the free fraction of all local anesthetics is increased in infants; therefore the maximum doses of all aminoamides must be significantly reduced in this age group even though the plasma concentration of AGP increases postoperatively, except in case of liver insufficiency.[12] On the other hand, with the stress of surgery, particularly in infants with infection or in an emergency surgery, plasma levels of AGP may increase.[10] The increase in plasma AGP concentration can change the proportion of free fraction of ropivacaine, increasing the plasma concentration of the bound fraction of this molecule and thus protecting from systemic toxicity of local anesthetic.[13] These phenomena can largely reduce the potential risk of local anesthetics after a single injection by retaining their plasma concentration within the safety margins.

RED CELL STORAGE. Once in the bloodstream, local anesthetics distribute to red blood cells, which retain 20% to 30% of the total dose, depending on the anesthetic and the hematocrit. Red cell storage usually has a minor impact on the pharmacokinetics of local anesthetics except in the following situations:

- In neonates: High hematocrit values (which may exceed 70%) and enlargement of erythrocytes (physiologic macrocytosis) result in consistent “entrapment” of local anesthetics, thus lowering peak plasma concentration (C_{max}) values after a single injection but increasing secondary release, thus increasing the half-life of all local anesthetics.
- In infants: Physiologic anemia reduces red cell storage and its protective effect against systemic toxicity of local anesthetics (after a single-shot injection only) when the plasma protein binding sites are saturated—that is, close to toxic blood concentrations.

ABSORPTION FROM THE EPIDURAL SPACE. Absorption of local anesthetics has been well studied in the epidural space. In children and infants, the same kinetics of absorption is reported, but the younger the patient, the less accentuated is the biphasic shape of the plasma concentration curve. The peak plasma concentration and the slope of the decreasing concentration curve are increased,[14] whereas the time (T_{max}) to reach C_{max} remains basically unchanged; for example, the T_{max} of bupivacaine is approximately 30 minutes regardless of the patient’s age.

Ropivacaine is a remarkable exception. After caudal or lumbar epidural injection, T_{max} is prolonged up to 2 hours in infants and C_{max} is increased.[15] This atypical pharmacokinetic profile may be explained by factors such as enzyme immaturity, slower systemic uptake, and decrease in distribution volume.[16,17] Intrinsic vasoconstrictive properties of ropivacaine also may play a role in the same way as the addition of epinephrine. This significant increase in both C_{max} and T_{max} values must be kept in mind because surgeries in infants are brief and the young patient may have left not only the operating room but also the postanesthesia care unit (PACU) less than 2 hours after the caudal or epidural procedure was performed, usually before peak plasma concentration is reached.

Importantly, levobupivacaine displays a similar pharmacokinetic profile. After caudal injection of levobupivacaine 2 mg/kg in infants younger than 2 years of age, the C_{max} range is 0.41 to 2.42 μg/mL (0.91 ± 0.40 μg/mL), which is higher than the C_{max} reported after caudal injection of the same dose of racemic bupivacaine.[18] T_{max} values also are delayed (50 vs. 30 minutes) in infants younger than 3 months of age as a result of reduced plasma clearance.[19]

When repeat injections are considered, the epidural dose must be reduced to keep C_{max} values in the same range as that resulting from the first injection. For the second injection, the following recommendations can be made:

- Reduce the dose to one third of the initial dose and do not inject it less than 30 minutes (lidocaine, mepivacaine, prilocaine) or 45 minutes (bupivacaine, levobupivacaine, ropivacaine) after the first injection;

or

- Inject half of the initial dose, but 60 minutes (lidocaine, mepivacaine, prilocaine, chloroprocaine) or 90 minutes (bupivacaine, levobupivacaine, ropivacaine) after the first injection.

If repeated injections are necessary, dosing should be further reduced to half of the second dose (i.e., one sixth of the initial dose) while respecting the same delay as for the second injection.

Continuous infusions aim to produce a steady-state concentration at the 24th hour postoperatively. This goal is easily achieved in adolescents with infusion rates of approximately 0.3 mg/kg/h of bupivacaine and levobupivacaine or 0.4 mg/kg/h of ropivacaine.

In infants, infusion rates must be reduced,[20,21] not exceeding 0.2 mg/kg/h with bupivacaine (or equipotent doses of other local anesthetics) in infants younger than 4 months and 0.25 mg/kg/h in older infants. Infants younger than 4 months (occasionally up to 9 months) may develop systemic toxicity even at these "safe" infusion rates with racemic bupivacaine because no steady-state plasma concentration is reached, even at 48 hours. In this age group, levobupivacaine[22] or ropivacaine[23] instead of racemic bupivacaine is preferred because stable plateau concentrations are obtained from the twenty-fourth hour onward.

ABSORPTION FROM OTHER INJECTION SITES. Absorption of local anesthetics deposited along mucous membranes is increased in infants.[24] Mucosal topical anesthesia has long been considered contraindicated in this age group. However, the technique can be safely used with certain precautions—selection of specific transmucosal patches[22] or sprays with diluted lidocaine[23,25] and recognition that topical lidocaine exaggerates laryngomalacia.[26]

After cutaneous application of EMLA (lidocaine and prilocaine) cream, peak plasma concentrations occur 4 hours later and remain low[27]—less than 200 ng/mL for lidocaine and less than 131 ng/mL for prilocaine, even in infants younger than 6 months of age.

Absorption of local anesthetics from compartment blocks (e.g., fascia iliaca, umbilical, ilioinguinal, pudendal blocks) follows the same biphasic curve as for the epidural space.[28-31] Because of the extended surface of absorption, injection of highly concentrated solutions of local anesthetics often leads to high, occasionally potentially toxic peak plasma concentrations, especially with 0.5% ropivacaine,[31] whereas use of more diluted solutions results in rather low plasma concentrations.

Absorption from peripheral nerve conduction blocks also follows a similar biphasic curve with different C_{max} and T_{max} values depending on the local anesthetic, the addition of epinephrine, and the site of injection; the more distal the injection, the slower is the absorption process (as in adults).

PULMONARY EXTRACTION. After they have reached the venous bloodstream and undergone plasma protein linkage and erythrocyte storage, aminoamides reach the right cardiac cavities and then the pulmonary circulation, from which they are extracted by the lung. Their plasma concentration in pulmonary veins and then in systemic arterial circulation (especially coronary and cerebral arteries) is consistently decreased. Thus pulmonary extraction represents a temporary protection against systemic toxicity. However, certain medical conditions suppress this protective effect. Some medications such as propranolol decrease pulmonary extraction in a clinically relevant way. Also, children with right-to-left shunts undergo considerable increase in arterial plasma concentration of local anesthetics because of pulmonary circulation bypass; even with small doses of local anesthetics they can develop systemic toxicity.[32]

DISTRIBUTION VOLUME. After intravenous injection, volume distribution at the steady state (Vd_{ss}) is 1 to 2 L/kg for all aminoamides (Table 76.2). After administration at other sites, calculated distribution is increased, often considerably, because of the "flip-flop" effect, especially for long-lasting local anesthetics. In infants and neonates, owing to higher extracellular fluid content (Table 76.3), the distribution volume of all local anesthetics is greater than in adults, the consequences of which are (1) significant decrease in peak plasma concentration of all local anesthetics, thus decreasing the danger of systemic toxicity after a single dose; and (2) accumulation with reinjections, which increases drug plasma concentration and elimination half-life while concomitantly decreasing clearance.

HEPATIC EXTRACTION AND CLEARANCE OF AMINOAMIDES. Short-acting local anesthetics undergo high hepatic extraction (0.65-0.75 ratio for lidocaine), which depends mainly on hepatic blood flow and not much on their plasma concentration. Only limited pediatric data are available for levobupivacaine. After a single injection, the clearance of levobupivacaine increases during the first months of life, but during continuous infusion (even with 0.0625% levobupivacaine), it tends to decrease almost to the same extent as that for racemic bupivacaine, and plasma concentrations do not reach a plateau.[19]

PLACENTAL TRANSFER. In pregnant women, placental extraction may consistently affect tissue distribution of local anesthetics. Protein binding influences placental transfer. The concentration ratio between umbilical venous blood and maternal arterial blood is approximately 0.73 for lidocaine, 0.85 for prilocaine, but only 0.32 for bupivacaine. Chirality may play a role, too, at least for bupivacaine, because placental transfer of D-bupivacaine exceeds that of L-bupivacaine but only with solutions containing epinephrine.[33] Most aminoesters undergo such a rapid plasma hydrolysis that placental transfer is not an issue. Tetracaine and cocaine, the hydrolysis of which is slow, are used only for topical applications or (tetracaine only) spinal anesthesia; systemic uptake is slow and plasma concentrations remain extremely low and thus are not issues again for placental transfer.

METABOLISM. Aminoesters are rapidly hydrolyzed by plasma cholinesterases. This enzymatic activity is low at birth (but no adverse clinical consequences are to be feared) and gradually reaches adult levels by 1 year of

TABLE 76.2 Age-Related Differences in Pharmacokinetic Parameters of Aminoamides

Local Anesthetic	Protein Binding (%)	Distribution Volume at Steady State (Vd_{ss})	Clearance (mL/kg/min)	Elimination Half-Life (h)
LIDOCAINE				
Neonate	25	1.4-4.9	5-19	2.9-3.3
Adult	55-65	0.2-1.0	11-15	1.0-2.2
MEPIVACAINE				
Neonate	36	1.2-2.8	1.6-3	5.3-11.3
Adult	75-80	0.6-1.5	10-13	1.7-6.9
BUPIVACAINE				
Neonate	50-70	3.9 (±2.01)	7.1 (±3.2)	6.0-22.0
Adult	95	0.8-1.6	7-9	1.2-2.9
LEVOBUPIVACAINE				
Infant	50-70	2.7	13.8	4
Adult	95	0.7-1.4	28-39	1.27 ± 0.37
ROPIVACAINE				
Infant	94	2.4	6.5	3.9
Adult	94	1.1 ± 0.25	4-6	1.15 ± 0.41

TABLE 76.3 Variation of Body Fluid Distribution by Age Group

Distribution of Body Fluids	Preterm Neonates (%)	Full-Term Neonates (%)	Infants (%)	Children (%)	Adults (%)
Total body fluids	80-85	70-75	65	55-60	50-55
Intracellular	20-25	30-35	35	35-40	40-45
Extracellular	55-60	45	30	20-25	20

age.[34] Chloroprocaine is eliminated at the fastest rate (4.7 mol/mL/h), procaine at a slower rate (1.1 mol/mL/h), and cocaine at only 0.3 mol/mL/h. Procaine and chloroprocaine are also metabolized, in part, by hepatic cholinesterases.

Aminoamides are metabolized within the liver, where they are subjected to two types of enzymatic reactions. Phase I reactions occur first, during which oxidation of the amide link is achieved within hepatic microsomes by the cytochrome P (CYP)450 enzyme superfamily, then phase II reactions, during which glucuronic acid or amino acid residues are appended to phase I metabolites, produce atoxic and water-soluble compounds, which are thus easily eliminated from the body.

CYP450 enzymatic activities are reduced during the first months of life. Bupivacaine is mainly metabolized by CYP3A4 in adults, but this enzyme is defective in infants. However, fetal CYP3A7 remains very active in infants, thus allowing metabolism of bupivacaine to be almost as effective as with CYP3A4.[24] Ropivacaine and levobupivacaine[19] are metabolized by CYP1A2, which is not fully functional before the third year, and, to a minor extent, by CYP3A4. This enzyme immaturity is clinically relevant but with limited consequences (lower clearance, delayed T_{max} and, for ropivacaine only, increased C_{max} but within clinically acceptable levels): it does not preclude administering these local anesthetics in neonates and infants.

Phase II reactions, especially glucuro-Vd_{ss} conjugation, are immature at birth and remain so until the third year of life. However, other conjugation pathways such as sulfoconjugation are active and quite effective during the first months of life.

ELIMINATION HALF-LIFE. Elimination half-life ($t_{1/2}\beta$) depends on both distribution and metabolism. It can be calculated using the formula below (*Cp* is the plasma clearance and Vd_{ss} the distribution volume at the steady state):

$$\frac{t_1}{2}\beta = (0.693 \times Vd_{SS})/Cp$$

Basically, $t_{1/2}\beta$ is the same in children older than 1 year of age and adults, mainly because the increase in Vd_{ss} is compensated by concomitant increase in *Cp* (related in part to higher hepatic blood flow in children, whose liver accounts for 4% of body weight, vs. only 2% in adults). Before the age of 1 year, *Cp* is low and elimination half-life of all local anesthetics is prolonged (see Table 76.2), thus favoring accumulation with repeat injections. Nevertheless, Bricker and colleagues[35] measured no consistent differences in pharmacokinetic parameters between infants and adults.

SYSTEMIC TOXICITY. Clinical signs of neurologic toxicity have been reported with plasma concentration ranging from 7 to 10 µg/mL for lidocaine or mepivacaine and 1.5 to 2 µg/mL (intraoperatively) to 2 to 2.5 µg/mL (postoperatively) with bupivacaine. However, plasma concentrations of bupivacaine higher than 4 µg/mL have been

TABLE 76.4 Commonly Used Additives and Recommended Doses in Pediatric Regional Anesthesia

Additive	Recommended Doses	Maximum Doses
MORPHINE		
Epidural	30 μg/kg	50 μg/kg
Intrathecal	10 μg/kg	20 μg/kg
Fentanyl (epidural)	1-1.5 μg/kg	2.5 μg/kg
Sufentanil (epidural)	0.25-0.5 μg/kg	0.75 μg/kg
Clonidine (epidural or along peripheral nerves)	1-1.5 μg/kg	2 μg/kg
Ketamine* (epidural or occasionally along peripheral nerves)	0.5 mg/kg	1 mg/kg

*Preservative-free ketamine (preferably preservative-free *S*-ketamine).

reported without evidence of clinical toxicity. From studies in adult volunteers, the following thresholds of toxicity of the unbound form of local anesthetics have been defined:

- 0.3 μg/mL for unbound bupivacaine
- 0.6 μg/mL for unbound levobupivacaine or ropivacaine

Because plasma protein binding is lower in infants, hazards of systemic toxicity might be increased, the more so as cardiac toxicity is usually concomitant with, not preceded by, central nervous system toxicity.

Opioids

Elimination half-life of neuraxial opioids is considerably increased in neonates and infants.[36] After epidural injection, morphine reaches its peak concentration in plasma within 10 minutes, but this concentration is very low and unable to provide clinically relevant analgesia.[35,37] Elimination half-life from cerebrospinal fluid (CSF) is similar to that from plasma, but CSF concentrations are very high after epidural injection; therefore it takes 12 to 24 hours before they decrease below minimal effective concentrations (near 10 ng/mL). Usual doses of neuraxial narcotics are listed in Table 76.4. Short-acting lipid-soluble opioids (fentanyl, sufentanil) can be used, but, as in adults, they do not significantly prolong postoperative pain relief unless repeat injections are given or a continuous infusion is established. Their analgesic effect is mainly a systemic effect, and the patient may experience acute respiratory depression (sudden apnea); this condition is very different from the progressive and delayed respiratory depression, preceded by generalized pruritus, sedation, and bradypnea, reported after excessive doses of epidural and intrathecal morphine.

Other Additives

Epinephrine 5 mg/L or 1/200,000 concentration is frequently coadministered with local anesthetics to decrease plasma peak concentration[28] and prolong the duration of blockade, especially in children younger than 4 years of age.[38,39] Another benefit expected from epinephrine is early detection of accidental intravenous injection (test dose) because young children are very sensitive to arrhythmogenic properties of epinephrine. Neuraxial epinephrine has long been suspected to potentially elicit spinal ischemia: even though this fear proved to be unfounded, many anesthesiologists recommend using lower concentrations of epinephrine (2.5 mg/L or 1/400,000) in local anesthetic solutions administered to neonates and infants; at such concentrations, the absorption rate of caudal bupivacaine is decreased by 25%.[39]

Clonidine, like epinephrine, is an α_2-adrenergic agonist that offers several benefits in children when added to local anesthetics either neuraxially[40-42] or peripherally (see Table 76.4)[43]; it increases (by a factor of ~2) the duration of nerve blockade without eliciting hemodynamic disorders, decreases plasma peak concentration of the local anesthetics, and produces a slight sedation for 1 to 3 hours postoperatively (which does not preclude hospital discharge). Addition of clonidine often eliminates the need for placement of a catheter to prolong postoperative pain relief, thus reducing morbidity and costs. However, its clearance in neonates is approximately one third of that in adults owing to immature elimination pathways[44] and several instances of respiratory depression in neonates and small infants have been reported[45,46]; this additive should be avoided during the first 6 months of life.[47]

Ketamine, especially S-ketamine, is an interesting adjuvant because of its blocking effects on *N*-methyl-D-aspartate receptors and interaction with sodium channels in a local anesthetic–like fashion (it shares a binding site with local anesthetics). Coadministered at a dose of 0.25 to 0.5 mg/kg, ketamine prolongs the duration of analgesia for many hours[41,48] with no significant adverse effects. This is not approved for use in the United States for this indication.

Many other agents have been occasionally used as adjuvants to local anesthetics.[49] Even though some of them proved to have analgesic properties (corticosteroids, buprenorphine, neostigmine, tramadol, and midazolam), they all produce significant adverse effects that preclude their use in most patients. Furthermore, their administration to pediatric patients raises ethical questions, and they are not approved for pediatric use in the United States.

PHYSIOLOGIC FACTORS

Surgery generates a neuroendocrine stress response in neonates, infants, and children,[4,50] resulting in undesirable alterations of the metabolic state and immune function.[51] Epidural anesthesia diminishes or even suppresses this stress response.[52-54] Central blocks do not affect left ventricular function and are virtually free of measurable hemodynamic effects, at least up to the age of 8 years.[55,56] Epidural anesthesia does not result in systemic or pulmonary hemodynamic changes as measured by mean blood pressure, end-diastolic diameter of the left ventricle, ejection fraction of the left ventricle, and mean velocity circumferential fiber shortening.[57] However, pulmonary Doppler flow velocity is decreased during epidural anesthesia, probably owing to an increase in the pulmonary arterial resistance. Preloading with saline is not recommended in children, and, even in adolescents, fluid therapy or injection of vasoactive agents is rarely required.

PSYCHOLOGICAL FACTORS

Children are frightened by new environmental conditions in the operating room, and most of them cannot cope with their anxiety.[58,59] They feel abandoned by their parents and exposed to strangers who are threatening them with needles. Furthermore, children younger than 10 years of age have not acquired their complete body image and cannot clearly make a distinction between adjacent parts of their body such as forearm and arm. Young patients cannot understand the concepts of paresthesia and differential blockade ("touch" is not "pain"). Thus localization of nerve trunks and anatomic spaces requires using physical methods independent of the patient's cooperation (loss of resistance [LOR] seeking, nerve stimulation, ultrasound techniques). Infants and most children cannot cope with their anxiety and fear of needles; therefore sedation or light general anesthesia may be needed before attempting a block procedure to avoid panic attacks and unwanted movements. Prospective regional anesthesia registries have demonstrated that awake versus asleep placement of regional blocks in children do not have any deleterious effects in outcomes.[60]

Regional anesthesia has a significant psychological impact. A pain-free postoperative course improves the morale of the patient, the family, and the nurses. Surgeons are happy to examine quiet, alert, and manageable patients. Occasionally, negative psychological effects can be observed—persistent motor (even sensory) blocks postoperatively may be frightening to some children (3-5 years of age especially) and their parents even though precise explanations had been given preoperatively as to the expected course of events during the postoperative period. Offering friendly environmental conditions, empathy, and additional explanations on local anesthetic pharmacology can reduce this postoperative anxiety.

Indications, Contraindications, and Complications

INDICATIONS

Indications for regional anesthesia in children are not identical to those in adults, not only because surgical pathologic processes are quite different but also because regional block procedures are used as techniques of analgesia in anesthetized children rather than in conscious or lightly sedated adult patients. There are data to demonstrate that performing regional anesthesia in children can be done with them asleep safely.[60,61]

Anesthetic Indications

Some children and adolescents are occasionally willing to undergo their surgery under regional anesthesia while remaining conscious. If a regional block can provide adequate analgesia, there is no reason to refuse such management, especially for short-duration surgery. Occasionally, such a management approach can be considered in children at risk for severe complications during general anesthesia from certain problems, such as the following[62]:

- Testicular torsion or incarcerated hernia at immediate risk for rupture in children who have nothing by mouth (NPO) guideline violation
- Inguinal hernia repair in former preterm infants younger than 60 weeks of postconceptual age who are at risk for developing severe postoperative apnea
- Severe acute or chronic respiratory insufficiency
- Emergency conditions in children with severe metabolic or endocrine disorders
- Neuromuscular disorders, myasthenia gravis, or some types of porphyria
- Some congenital syndromes and skeletal deformities

Cervical instability (making tracheal intubation a risk for tetraplegia) is seen in children with Chiari malformation, achondroplasia, and Down syndrome. Patients with facial deformities, microstomia, metabolic disorders like Hurler and Hunter syndromes and mandibular hypoplasia can be difficult to intubate, thus making general anesthesia less safe. Also, infants with epidermolysis bullosa are extremely difficult to manage under general anesthesia; occasionally, regional block procedures may represent an alternative with lower morbidity.[63-65] Trauma patients with extremity lesions may greatly benefit from peripheral nerve block for alleviating pain without impeding monitoring and evaluation of head trauma or hemodynamic disorders and allowing wound dressing as well as temporary stabilization of fractures, provided that appropriate precautions are taken to avoid masking development of compartment syndromes (see later).

Intraoperative and Postoperative Analgesia and Procedural Pain

Analgesia is currently the main indication for regional blocks in children because they offer the best risk-benefit ratio for many outpatient and inpatient surgeries: orthopedic (including scoliosis surgery), thoracic, urologic, and upper and lower abdominal surgeries.[66-68] Cardiac surgery is a more controversial indication,[69,70] and many anesthesiologists are reluctant to perform neuraxial blocks in children scheduled to receive anticoagulants although this is changing with more recent guidelines from the American Society of Regional Anesthesia and Pain Medicine (ASRA) regarding heparinization after 60 minutes of placing the block.

Procedural pain can easily be anticipated and thus prevented mostly by topical anesthesia or infiltration techniques.[71-73] The indications for perineural catheters depend on the expected duration of postoperative pain.[74] Also, surgery associated with intense postoperative pain (major orthopedic surgery, hand or foot amputation) and postoperative pain management or painful physical therapy necessary for several days (knee arthroscopy and repair) are excellent indications for catheters.[75]

A comparative evaluation of suitability, and risk-benefit ratio for most regional techniques is provided in Table 76.5.

Management of Nonsurgical Pain

Relief of pain associated with some medical conditions such as herpes zoster, acquired immunodeficiency syndrome (AIDS), mucosal and cutaneous lesions, and cancer can be achieved using regional block techniques.[76,77] Children with sickle cell disease may greatly benefit from epidural analgesia during vasoocclusive crisis or thoracic syndromes with intractable pain by other means, provided that pain is localized to limited areas and concomitant fever is not due to bacteremia.[78,79]

Chronic Pain Relief and Palliative Care

Chronic pain is less unusual in children than commonly believed, and regional techniques such as epidural anesthesia, stellate ganglion blockade, or continuous peripheral nerve blocks may help treat this condition, especially in case of phantom limb pain and complex regional pain syndrome (CRPS), leading to pain reduction (minimal pain scores), facilitating physiotherapy, and functional rehabilitation.[80] Treatment of intractable refractory pain from a chronic dislocated hip with long-time perineural catheter has been described.[81] Erythromelalgia, a rare but extremely painful condition, can be successfully relieved by continuous epidural analgesia.[82] Cancer pain resulting from either primary tumor or metastases also can be controlled by regional techniques when other medications fail or produce too many adverse effects. Virtually all techniques of regional anesthesia have been reported in this ultimate management of pain in children, from epidural analgesia to intrathecal infusions to celiac or brachial plexus block.[83,84]

Nonanalgesic Indications

For certain medical conditions, analgesia is not the only benefit expected from regional blockade. Sympathetic blockade is essential to protect and improve blood supply to an upper or lower extremity in a context of severe trauma. Also, continuous epidural blockade proved to be effective in treating vascular insufficiency resulting from Kawasaki disease, accidental intra-arterial injection of an anesthetic drug,[85] penile block with a local anesthetic containing epinephrine, and severe frostbite. Axillary and stellate ganglion blocks have also successfully treated acute vascular insufficiency of the upper limb.[86]

TABLE 76.5 Evaluation of the Suitability and Benefit-to-Risk Ratio and Feasibility With Ultrasound Guidance of Most Techniques of Regional Anesthesia in Children

Technique	Ease of Performance	Benefit-to-Risk Ratio	Feasibility With Ultrasound	Catheter Placement
CENTRAL BLOCKS				
Spinal block	+ to ++	+++	Mild	No
Caudal block	+++	++++	Easy	Occasionally
Lumbar epidural anesthesia	+++	+++	Difficult	Yes
Thoracic epidural anesthesia	+++	+++	Difficult	Yes

Wound infiltration	++++	+++	No	Yes
Topical anesthesia	++++	++++ (skin)	No	No

CONTRAINDICATIONS AND LIMITATIONS

Absolute Contraindications to Neuraxial Blocks

Medical conditions that contraindicate neuraxial blocks in children are (1) severe coagulation disorders, which may be constitutional (hemophilia), acquired (disseminated intravascular coagulation), or therapeutic; (2) severe infection such as septicemia or meningitis; (3) intracranial tumor with increased intracranial pressure; (4) true allergy to local anesthetics (a very rare condition even with aminoesters); (5) certain chemotherapies (such as with cisplatin) prone to induce subclinical neurologic lesions that can be acutely aggravated by a block procedure; (6) uncorrected hypovolemia; and (7) cutaneous or subcutaneous lesions, whatever their nature (infection, angioma, dystrophic, tattoo) at the contemplated site of puncture. Parental refusal is a nonmedical absolute contraindication.

Depending on the clinical condition of the patient and the possibility to cure (at least temporarily) the impeding disorder, a regional block may be considered in spite of the existence of a contraindication. After correction of hypovolemia, injection of factor VIII to a hemophilic child, or effective antibiotic treatment of a septicemic patient,[87] a central block may be performed, provided that the expected benefits consistently outweigh the risks by comparison with other techniques of analgesia. Also, some authors consider it acceptable to perform a caudal block in children with shunt devices under protection of antibioprophylaxis.[88] In a single-center study, it was demonstrated that caudal blocks in children with VP shunts can be safely performed.[89]

Absolute Contraindications to Peripheral Nerve Block Procedure

True allergy to local anesthetics is the only absolute medical contraindication to peripheral nerve blocks. Coagulation disorders are less hazardous than during neuraxial blocks, but it is prudent to avoid techniques with a danger of arterial trauma, especially in an area where compression is difficult or impossible (infraclavicular brachial plexus block, psoas compartment block).[61] Septicemia does not necessarily contraindicate peripheral nerve blockade if expected benefits are significant. Local skin infection at the puncture site should be considered before performing a peripheral nerve block, especially if a catheter is implanted. Hypovolemia should preferably be corrected but does not preclude peripheral blocks because hemodynamic consequences are minimal.

Patients at Risk for Compartment Syndrome

Because pain is one of the cardinal symptoms of a compartment syndrome, any pain treatment, including regional anesthesia, is often claimed to be contraindicated because it can suppress this manifesting symptom, thus delaying the rescuing surgery. Such a refusal of pain management is not acceptable either medically and ethically.[90] Fractures are very frequent in the pediatric population, whereas compartment syndromes are very rare; whether or not a compartment syndrome is in progress, intense pain is a constant feature. Adequate pain management, including continuous epidural analgesia,[91] does not preclude early diagnosis, and this fact was confirmed by the National Pediatric Epidural Audit in Great Britain.[92]

The European Society of Regional Anaesthesia and ASRA collaboration recently published guidelines for the use of regional anesthesia and compartment syndrome.[61]

Excruciating pain is not a "manifesting" symptom but a late symptom of compartment syndrome. Patients at risk should be monitored adequately, which is not done most of the time even in university hospitals, and precautions must be taken including avoidance of closed plaster casts; elbow immobilization with an angle greater than 90 degrees[93]; closed reduction of supracondylar fractures of the humerus; repeat clinical evaluation of the distal perfusion and tissue oxygenation of the limb; and noninvasive monitoring of the intracompartmental pressure, even though this monitoring is not 100% reliable. If the risk is considered high (e.g., displaced humeral fractures, intramedullary nail fixation of tibia or radius, obtunded patients), intracompartmental pressure close to the fracture site should be invasively monitored. The procedure is easy and almost inexpensive, requiring only a venous cannula, an intravenous line, and a pressure gauge (as for central venous pressure measurement).[94,95]

Hemoglobinopathies

Children with sickle cell disease are prone to develop hemolysis in case of desaturation and undergo repeat episodes of extreme pain as a result of extended microthromboses when local blood flow slows down (e.g., hemoconcentration, shock, surgical tourniquet).[96] In the case of a danger of hypoxemia (respiratory disease) or hemodynamic disorders (surgery known to produce significant blood loss, tourniquet placement), regional (especially neuraxial) blocks should be avoided. Regional anesthesia has been shown to improve symptoms in children with sickle cell disease and decrease their pain.[78]

Bone and Joint Deformities

Minor or localized malformations of the spine (hemivertebra, spina bifida occulta, Scheuermann disease) do not preclude neuraxial blocks, whereas extended malformations of vertebrae, spinal fusion, myelomeningoceles, open spina bifida, and major spondylolisthesis are relative contraindications.[89] Tethered cord syndrome is not unusual and is often misdiagnosed. The diagnosis must be suspected if a clump of hairs or a dystrophic lesion of the skin is present at the lower extremity of the spinous process line or in the case of minor neurologic disorders involving pelvic nerves (minimal sphincter disorders, perineal dysesthesia). This can be diagnosed using ultrasound guidance. Although some authors consider that this condition is not a contraindication,[97] it is preferable to select another technique of analgesia than epidural blockade.[89] Many pediatric syndromes, cerebral palsy, and kyphoscoliosis are associated with bone and joint deformities that represent more of a technical difficulty than a contraindication to performing a regional block.

Preexisting Neurologic Disorders or Diseases

Controlled epilepsy is not a contraindication to regional anesthesia, including neuraxial blockade. Preexisting central nervous system disorders and degenerative axonal diseases have long been considered to be contraindications, at least relative, even though no data support the hypothesis that a regional block could worsen their course.[98]

COMPLICATIONS

Complications of regional anesthesia are essentially the same as those in adults. The complication rate found recently in a large epidemiologic study was 0.12%, with two major risk factors—age and the central blocks.[99] They can be classified as local, regional, and general (or systemic).

Local Complications

The four main types of local complications are as follows:

1. Inappropriate needle insertion damaging the nerve and surrounding anatomic structures
2. Tissue coring and introduction of epithelial cells into tissues where they do not belong and where they can develop as compressive tumors (especially in the spinal canal)[100]
3. Injection of neurotoxic solutions (syringe mismatch, epinephrine close to a terminal artery)
4. Leakage around the puncture site, especially when a catheter has been introduced, which may cause partial block failure and favor bacterial contamination (very rare)

These local complications are easily avoidable by using adequate devices and applying standard precautions (appropriate dressing and bacterial precautions). Tunneling the catheter and applying a slightly compressive dressing can reduce leakage around the catheter.

Local anesthetics are locally toxic. Myelin, effective protection of nerve roots, is less abundant or absent in children, potentially making the nerves more sensitive to local anesthetics. In animals, it has been clearly demonstrated that the sensitivity of nerve fibers to local anesthetics is inversely correlated with age.[101] However, in most cases, perineural injection is around muscle. The myotoxicity of local anesthetics has been previously demonstrated in humans and animals,[102] primarily through mitochondrial damage. This also has been demonstrated in young animals.[103] By comparing continuous bupivacaine perineural administration in adult rats and young rats, the authors showed that muscle, mitochondrial, and ultrastructural toxicity was significantly greater in the juvenile group,[103] thus emphasizing the need to use lower dosages in younger patients.

Systemic Complications

Systemic complications usually result from accidental intravenous injection of local anesthetics or, less frequently, excessive dosing.[9,104] Systemic toxicity is essentially of two types: neurologic and cardiac resulting from heart failure by blocking sodium and potassium channels. Early signs of neurologic toxicity (tinnitus, malaise, metallic taste in the mouth) are unfortunately masked by general anesthesia. The main complications are heart conduction disorders, cardiac arrhythmias (bradycardia or tachycardia), and atrioventricular block. QRS widening, bradycardia, and torsade de pointes are followed by ventricular fibrillation, asystole, or both.[105] Nevertheless, signs of cardiac and neurologic toxicity occur at lower plasma concentrations of bupivacaine than ropivacaine.[106] This toxicity may be aggravated by a decrease in plasma binding protein, mainly AGP, resulting in a greater proportion of the unbound form of local anesthetic. The plasma concentration of this protein is low at birth, and tends to increase with the age of the child to reach values equivalent to those of adults at the age of 10 months.[107] However, special care must be taken during continuous injections; the dosage of local anesthetic should be systematically reduced in very young children or after prolonged administration (>48 hours).

Systemic complications can be life threatening and should be managed in the same way as in adults. The major difference between adults and children is that cardiovascular complications are not preceded by neurologic signs but are concomitant with cerebral toxicity.[108] In addition to pharmacokinetic factors, the rapid heart rate of children may increase the risk for cardiac toxicity induced by local anesthetic toxicity. Even if toxic events occur with ropivacaine, small doses of epinephrine should produce rapid recovery. Impaired ventricular conduction is the primary manifestation of local anesthetic toxicity. Treatment includes oxygenation, cardiac massage, and epinephrine, which is given in small incremental boluses beginning with 1 to 2 μg/kg.[109] If ventricular fibrillation persists, defibrillation (2-4 J/kg) is performed. Although resuscitation measures must be initiated immediately, the specific treatment of local anesthetic toxicity is rapid administration of Intralipid.[109] The recommended dose of 20% Intralipid for pediatric patients is 2 to 5 mL/kg by intravenous bolus. If cardiac function does not return, this dose (up to 10 mL/kg**)** is repeated.[24]

Epidemiology

Available pediatric information is limited. The first report of the American Society of Anesthesiologists (ASA) closed claims analysis contained 238 pediatric cases (10% of claims), but only 7 involved children who received regional anesthesia[110]; however, at that time regional anesthesia was not commonly used in children, making this apparently low rate of complications meaningless. In 1996, the 1-year prospective study of the French-Language Society of Pediatric Anesthesiologists evaluated 85,412 pediatric anesthetic procedures, including 24,409 involving regional anesthesia.[111] Twenty-three complications (no sequelae, no death, and no legal consequences) were found, all following neuraxial blocks. In 2000, the Australian Incident Monitoring Study[112] included 2000 claims involving 160 pediatric cases with a regional block procedure (83 epidurals, 42 spinals, 14 brachial plexus, 4 Bier blocks, 3 ophthalmic blocks, and 14 local infiltrations). The largest single cause of complications was circulatory problems; 24 drug errors (including 10 "wrong drugs" and 14 "inappropriate use") were found. In 2007, the British National Pediatric Epidural Audit[92] reported 96 incidents in 10,633 epidural blocks performed, as follows:

- Fifty-six (0.53%) were associated with the insertion or maintenance of epidural anesthesia, and most were of low severity; only one child had residual effects from cauda equina syndrome (after a programming error of the infusion pump).
- Forty (0.38%), mainly pressure sores,[92] were believed to be associated with the epidural infusion technique.

A significantly higher rate of incidents occurred in the neonatal age group, mainly because of drug errors (13 cases) and local anesthetic toxicity (1 case); these incidents were not related to catheter insertion. Twenty-eight infection-related incidents occurred, of which 85% were relatively minor skin infections; caudal catheters did not result in increased incidence of infections. Six children older than 8 years of age had mild postdural puncture headache. Four patients developed a compartment syndrome, but the condition was not masked by the epidural infusion.

From November 2005 to October 2006, a large epidemiologic study recorded the characteristics and developments of regional anesthesia in children in 47 French hospitals.[99] As previously demonstrated by Rochette and colleagues,[113] the authors reported a radical change in regional practice among French anesthesiologists with a transition from using predominantly neuraxial blocks to peripheral nerve blocks, including catheter techniques. A recent 1-year prospective survey of regional anesthesia evaluated complications and side effects in 31,132 cases of regional anesthesia. Complications (41, involving 40 patients) were rare and usually minor and did not result in sequelae. The study recorded a very low overall rate of complications of 0.12%, significantly six times lower for peripheral blocks than for neuraxial blocks. Age was also a risk factor, because the incidence of complications was higher before 6 months of life than after (0.4% vs. 0.1% after 6 months of life). Fifteen cases of cardiotoxicity were observed, of which 87% occurred with a central block. The occurrence of complications does not seem to increase with the use of catheters.

A large North American Regional anesthesia registry (Pediatric Regional Anesthesia Network- PRAN) has just published prospective data on 100,000 blocks in over 20 centers. The incidence of systemic toxicity was 0.76:10,000 cases with the majority occurring in infants. No permanent neurologic deficits were reported; however the risk of transient neurologic deficit was 2.4:10,000 and was not different between peripheral and neuraxial blocks.[114]

In conclusion, regional block procedures—mainly neuraxial blocks—are associated with the occurrence of adverse incidents (~0.5%) that are mostly minor but occasionally severe. The majority of these complications result from insufficient precautions at the time of the block procedure (drug errors) and postoperatively (pressure sores). Also, of major importance is the fact that compartment syndrome is not hidden by regional anesthesia provided that adequate monitoring is guaranteed.[61]

Selection of Materials and Anesthetic Solution

SELECTION OF BLOCK PROCEDURE

Careful selection of block procedures is based first on anatomic considerations. Sensory blockade must cover all areas from which noxious stimuli can originate (e.g., operative field, sites for skin or bone graft tissue, placement of tourniquet or drains). Then, the potential morbidity of the technique, from the medical condition of the patient, the requested positioning, or the "intrinsic" morbidity of the technique itself, must be evaluated. The anticipated duration of postoperative pain is the third most important factor to take into account because the regional technique should provide adequate analgesia until minor analgesics are sufficient. The anesthesiologist will select one of the following approaches:

- A single-shot technique with either a short-acting or a long-acting local anesthetic
- A single-shot technique with local anesthetic and adjuvants
- A catheter technique with repeat or continual injections of local anesthetic

SELECTION OF EQUIPMENT

Epidural anesthesia (sacral, lumbar, or thoracic) is performed using Tuohy needles ranging in size from 17 to 21 gauge and in length from 50 to 90 cm; shorter Tuohy needles (25 cm) would be more appropriate in neonates and infants but are not easily available. Caudal anesthesia has been performed in the past with almost all types of needles. This is no longer acceptable, and only short beveled needles (Crawford needles) with a guide sealing their lumen or intravenous cannulas with an introducer needle should be used. Ultrasound guidance has not been introduced for placement of epidural catheters in neonates and infants with greater precision and less complications.[115]

Spinal anesthesia in premature infants can be performed using either a neonatal lumbar puncture needle (22 gauge) or, preferably, a thinner spinal needle (shorter than 50 mm). The distal end of the needle does not have the same importance as in adults because the incidence of postdural puncture headache remains low in children and may not be influenced by the design of the tip of the needle.[116,117] What matters most is the distance separating the tip of the needle from its distal orifice; this distance must be as short as possible to avoid extradural leakage if the needle has not been introduced far enough through the dura mater. Pencil-point needles have no advantage in infants and young children; they do not improve the results and are even suspected to decrease the success rate by favoring subdural spread of the local anesthetic. A summary of recommended needles for most regional block procedures in pediatric patients is provided in Table 76.6.

SELECTION OF DRUG

The prerequisites for selecting a local anesthetic are not exactly the same in children as in adults because regional techniques are mostly used for analgesic purposes rather than anesthesia. The factors to be considered are (1) site and severity of surgery, (2) expected duration of intense postoperative pain, and (3) hospital stay versus early discharge. Usual doses are listed in Table 76.7.

Lidocaine, chloroprocaine, and mepivacaine are preferred for outpatient surgery. For inpatient surgery, ropivacaine, levobupivacaine, and bupivacaine are commonly used. Nevertheless, it is now recommended that L-enantiomers be used especially for continuous infusions; they are well known for their lower cardiac toxicity compared with bupivacaine.[118] The pharmacologic characteristics of ropivacaine can achieve a differential nerve block[119] and have limited myotoxicity in contrast to bupivacaine.[120] After

TABLE 76.6 Recommended Devices for Most Regional Block Procedures in Children

Block Procedure	Recommended Device	Alternate Device
Intradermal wheals and metacarpal blocks	Intradermal needles (25 gauge)	None
Subcutaneous infiltrations and field blocks	Standard intramuscular needles (21-23 gauge)	Intradermal needles (25 gauge)
Compartment blocks (thoracic paravertebral, rectus sheath, ilioinguinal-iliohypogastric, pudendal, penile)	Short (25-50 mm) and short beveled (45-55 degrees) needles	Epidural needles (intercostal block) Neonatal spinal needle
Peripheral mixed nerve blocks and plexus blocks	Insulated 21-23 gauge short beveled needles of appropriate length connected to a nerve stimulator (0.5-1 mA) Specific catheter (for continuous techniques)	Sheathed pencil-point needles Unsheathed needles only when ultrasound guidance is used Epidural catheter (for continuous techniques)
Spinal anesthesia	Spinal needle (24-25 gauge; 30, 50 or 100 mm long, Quincke bevel, stylet)	Neonatal lumbar puncture needle (22 gauge, 30-50 mm long) Whitacre spinal needle
Caudal anesthesia	Short (25-30 mm) and short beveled (45-degrees) needle with stylet	Intravenous cannula (22-18 gauge), especially for epidural catheter insertion Pediatric epidural (occasionally spinal) needle
Epidural anesthesia	Tuohy needle (22, 20, and 19/18 gauge); LOR syringe and medium epidural catheter	Crawford, Whitacre, or Sprotte epidural needles appropriately sized; LOR syringe and medium epidural catheter

LOR, Loss of resistance.

TABLE 76.7 Usual and Maximum Recommended Doses of Local Anesthetic for Conduction Nerve Blocks (Excluding Bier Blocks and Spinal Anesthesia)

Local Anesthetics	Usual Concentration (%)	Maximum Dose of Plain Solution (mg/kg)	Maximum Dose With Epinephrine (mg/kg)
AMINOESTERS			
Procaine	1-2	7	10
Chloroprocaine	2-3	7	10
AMINOAMIDES			
Lidocaine	0.25-2	5 (or 400 mg)	10 (or 700 mg)
Mepivacaine	0.25-2	5-7 (or 400 mg)	Not available
Bupivacaine	0.125-0.5	2 (or 150 mg)	3 (or 200 mg)
Levobupivacaine	0.125-0.5	3 (or 200 mg)	4 (or 250 mg)
Ropivacaine	0.1-10	3 (or 300 mg)	Not available (and not recommended)

extravascular injection, the plasma concentration of ropivacaine peaks later than that of bupivacaine, sometimes up to more than 2 hours after injection.[17] This delay in the peak plasma concentration of ropivacaine usually reduces the maximum plasma concentration, providing some security in terms of toxicity, as demonstrated in some pediatric studies.[17,121] Even if the plasma concentration of free and total ropivacaine is higher in younger children, plasma concentrations of ropivacaine and its main metabolite (2,6-pipecoloxylidide) are not influenced by the duration of infusion of local anesthetics. In infants younger than 3 months of age, epidural infusion of ropivacaine should not be maintained for more than 36 hours.[122] The clearance of ropivacaine increases with age but remains unchanged throughout the infusion in each age category. Ropivacaine appears to be more predictable, and safer during continuous infusion for 48 to 72 hours than bupivacaine; the plasma concentration of bupivacaine increases and clearance decreases in proportion to the duration of infusion.[12] Studies examining the pharmacokinetics of local anesthetics during continuous perineural administration are rare in children. The safety of continuous regional anesthesia techniques in children relies on the use of low-concentration solutions accompanied by low plasma concentrations of local anesthetics and limit the risk for systemic toxicity of these molecules. Addition of clonidine or ketamine helps improve the quality and duration of blockade without precluding early hospital discharge. In many cases, these drugs make it unnecessary to insert a catheter and establish a continuous infusion to provide adequate postoperative pain relief.

For many years, continuous epidural anesthesia was the only suitable technique for treating protracted pain. In recent years, peripheral nerve catheter techniques have proved to be effective,[67] with less morbidity and limitations than continuous epidural blockade, even allowing hospital discharge[80] and management at home in selected pediatric patients. For these techniques, continuous infusion (2-5 mL/h) or on-demand injections (2-5 mL) of low-concentration levobupivacaine or ropivacaine (0.1%-0.2%) represents the best and safest choice.

Patient-controlled administration of continuous infusion seems to be better in children, allowing decrease of the dose of local anesthetics for the same quality of analgesia.[123,124] Duflo and associates[124] comparing standard continuous administration (0.1 mL/kg/h) and patient controlled regional anesthesia regimen (infusion of 0.02 mL/kg/h and bolus of 0.1 mL/kg every 30 minutes) of 0.2% ropivacaine in patients undergoing fascia iliaca compartment or sciatic catheters noted lower hourly consumption of ropivacaine in patient-controlled administration. Ropivacaine plasma levels were also lower in this group in contrast to standard administration (0.31 and 0.86 mg/mL at 24 hours and 0.31 and 0.52 mg/mL at 48 hours). In a recent study, plasma levels of ropivacaine were collected and compared with continuous epidural block and continuous psoas compartment block in children.[125] The dose of local anesthetic infusion was 0.2 mg/kg/h of 0.2% ropivacaine in the continuous psoas compartment block. The median plasma concentrations of ropivacaine did not exceed 0.59 μg/mL in this patient group and was lower than the plasma concentration in the epidural catheter group. Recent studies demonstrating blood levels of bupivacaine in adolescents with indwelling continuous catheters showed safety in these infusions at home.[126]

Anatomic Identification in Regional Anesthesia

MANUAL APPROACHES

The success of a regional anesthesia technique depends on the administration of a solution of local anesthetic close to the nerve or space limited by anatomic structures. Few nerve blocks can be performed using a manual approach without the aid of a nerve stimulator or ultrasound. These techniques are feasible in children anesthetized or sedated.

Some important consideration for performing regional anesthesia without any additional equipment include:

- Possessing good knowledge of the anatomy of the child according to age and good location of landmarks for the puncture site
- Defining the anatomic space at which the local anesthetic spreads to block the selected nerves
- Ensuring no risks exist for damage to other surrounding structures (e.g., vessels, nerves, organs)

Central blocks (caudal, epidural, or spinal block) are among the blocks that primarily can be achieved without assistance from technical devices, even though ultrasound-guided techniques for punctures are currently proposed. The realization of epidural block is facilitated by the LOR technique. For the spinal block, passing into the subarachnoid space is marked by the crossing of the dura mater (tough fibrous structure): a slight LOR is felt, and then the flow of CSF. For the caudal block, the passage of the sacrococcygeal membrane is felt by an increase and LOR in the needle. The majority of limb peripheral nerve blocks are performed using a nerve stimulator or with ultrasound guidance. Blocks of the trunk, performed with anatomic landmarks techniques for a long time, benefit greatly from ultrasound guidance for their localization. The pudendal block, even if it is done using anatomic landmarks, also can benefit from using the nerve stimulator to be closer to the nerve[127] or ultrasound guidance.[128] The superficial trigeminal nerve blocks on the face, described by anatomic landmarks for a long time, can now benefit from ultrasound guidance for the puncture.[129] Finally, older techniques, such as the paresthesia technique, transarterial techniques for the axillary block, and “swoosh” (test of good hand position by auscultation with a stethoscope of the caudal vertebrae low back during the injection of liquid into the needle) test for caudal block, should no longer be used.

Electrical Stimulation

Ultrasound guidance represents a revolution in regional anesthesia in children and adults. Despite its increasing use, electrical stimulation remains the gold standard of nerve location in adults and children. Nerve stimulation equipment has largely improved and is clinically safer. The location of needle entry point before puncture can reduce the number of attempts and decrease the potential risk for nerve injury.[130]

For plexus and truncal nerve blocks, the anesthesiologist should use a nerve stimulator to elicit muscle twitches. The positive electrode of the nerve stimulator is placed distant to the nerve location. The nerve stimulator delivers square-wave electric impulses lasting 50 to 100 microseconds at the rate of 1 to 5 Hz. With a starting output of 2 to 2.5 mA, needles are advanced until they elicit the required muscle movement. The position is judged adequate when muscle contractions continue to occur at a current of 0.5 to 0.8 mA, when the tip of the needle is approximately 1 mm from the nerve or within the perineural fascial sheath. In contrast to adults, in whom a current of 0.5 mA or less is considered an acceptable indicator for a successful nerve block,[131] in children, if muscle contractions are still present at a current under 0.5 mA, the needle should be withdrawn to avoid intraneural injection and nerve damage.[132] Gurnaney and colleagues[133] evaluated the relationship between the lowest current amperage used to obtain a motor response, the success rate, and the incidence of neurologic complications with peripheral nerve blocks in pediatric patients under general anesthesia. The authors observed a similar peripheral nerve block success rate with both a low (<0.5 mA) and a high stimulation threshold (0.5-1.0 mA). They concluded that it may not be necessary to perform needle manipulation in close proximity to the nerve to achieve a low stimulation threshold (<0.5 mA), because it may increase the risk for intraneural injection. Most importantly, in performing peripheral nerve blocks in anesthetized children, the needle should not be intrafascicular. The disappearance of the motor response by reducing the intensity under 0.5 mA for 0.1 ms, confirms that the tip of the needle is not in contact with axons. In adults, Bigeleisen and associates[134] revisited the relationship between minimum stimulating current and intraneural needle placement in a clinical investigation comparing intraneural and extraneural stimulation thresholds in ultrasound-guided supraclavicular block. Intraneural stimulation thresholds in excess of 0.2 and less than 0.5 mA were observed in 54% of patients. In 10% of patients, the stimulating threshold exceeded 0.5 mA when the needle was in an intraneural location. Thus a response obtained for a current intensity less than 0.2 mA for 0.1 msec may be associated with an intrafascicular position of the needle and should be avoided.

Peripheral nerves are not as deep in children as in adults and can be located percutaneously. By using surface nerve mapping technique the success rate of peripheral nerve blocks in children can be improved.[135] Nerve mapping helps locate the needle entry point before puncture, thereby reducing the number of attempts and decreasing the potential risk for nerve injury.

Nerve stimulation can be used for ultrasound guidance training. Concomitant use of nerve stimulation can increase the confidence of the trainee while lessening the anxiety of the attending instructor. Other common sources of error during novice practice and beyond include failure to distinguish between adjacent isoechoic structures.[136]

Ultrasound Techniques

Ultrasonographic guidance for regional anesthesia in children has seen considerable interest recently. The benefit of this technique is the visualization of targeted nerves or spaces and the spread of injected local anesthetic.

The majority of peripheral nerves for regional anesthesia can be visualized in children using US guidance. However, the nerves are not static structures and can move, depending on the position of the child, pressure of the probe to the skin, and progression of the needle or injection of local anesthetic. In children, a linear ultrasound probe with a 25-mm active surface area (or probes with 38 mm of active surface area in older children) provides a square image that is not deformed. Probes with frequencies of 8 to 13 MHz offer excellent resolution for superficial structures of the upper limb (e.g., axillary block) and good penetration depth for the lower extremity (e.g., popliteal block). The higher frequencies could provide images that will be sharp for superficial structures. In principle, the needles typically used to perform peripheral nerve blocks can be used with ultrasound guidance. In vitro, results have shown that visualization of the needle depends on its diameter and mainly the angle of penetration.[137] Use of a facet-tipped needle for peripheral nerve blocks facilitates precise placement of the needle with minimal pain for the child,[138] which seems particularly interesting for blocks performed in children without sedation or general anesthesia. Sterile preparation of the probe and the block site is an important prerequisite for ultrasound-guided blocks. A sterile probe cover should be used for single and continuous block techniques.

The easier ultrasound-guided blocks are axillary blocks, femoral blocks, fascia iliaca compartment blocks, caudal blocks, ilioinguinal blocks, and paraumbilical blocks.[139] They permit a safe and easy learning curve of these techniques. The main advantage of ultrasound-guided regional anesthesia is the visualization of different anatomic structures and the approximate localization of the tip of needle. The other advantages for ultrasound-guided peripheral nerve blocks in children are faster onset time of sensory and motor block, longer duration of sensory blockade,[138] increase of blockade quality,[138,140] and reduction of local anesthetic injections.[140,141] The use of ultrasonographic guidance for central block allows visualization of different structures, spine, and spinal contents. Spinous process, ligament flavum, dura mater, conus medullaris, and CSF are identifiable, and give some information on spine, epidural space, and the depth between epidural space and skin.[142] Finally, in a caudal block, ultrasound imaging permits evaluation of the anatomy of the caudal epidural space, especially the relation of the sacral hiatus to the dural sac, and the search for occult spinal dysraphism.[143] Recently, ultrasound imaging showed its superiority over the swoosh test when performing a caudal block.[144] Anterior displacement of the posterior dura mater during saline or local anesthetic injection is a predictor of block success. This ultrasound-guided puncture improves the efficacy and safety of the central blocks by reducing the number of punctures. Unfortunately, the image quality is rapidly altered with ossification of the structures occurring in older children.[145]

A recent Cochrane review suggested that ultrasound guidance provided greater accuracy, reduced doses in younger children, fewer needle insertions, and better user appreciation of the anatomy.[1] A comparative evaluation of feasibility with ultrasound guidance for most regional techniques is provided in Table 76.5.

Safety, Precautions and Discharge Criteria

ACCEPTABLE ENVIRONMENTS FOR PERFORMING A REGIONAL BLOCK

Regional techniques are techniques of anesthesia; therefore they must be performed only in places where all the monitoring, anesthetic, and resuscitation equipment (including anesthetic and emergency drugs) is available. Additionally, the anesthesiologist must be assisted by staff members able to provide adequate patient monitoring and trained to help in emergency situations. Most blocks should be done in the operating room unless the patient is an older teenage adolescent who may be willing to allow performance of a block in the preoperative area.

SEDATION AND GENERAL ANESTHESIA

Regional procedures are performed in conscious adult patients, with or without sedation, but usually not under general anesthesia. In some pediatric patients, the same management can be offered and is sometimes requested by the child.[144] However, most children require being unconscious during the block procedure. If general anesthesia is not medically contraindicated, it is widely accepted that regional blocks be performed with the patient under light general anesthesia; large databases have demonstrated safety.[68,99,114,147]

PATIENT MONITORING AND SAFETY PRECAUTIONS DURING THE BLOCK PROCEDURE

Monitoring and Anesthesia Chart

Even if general anesthesia is not used and the surgical procedure is primarily based on a regional technique, the anesthesiologist should always apply routine intraoperative monitoring, including electrocardiographic (ECG) tracings and blood pressure, temperature, respiratory rate, and oxygen saturation measurements. An intravenous line must be established before any injection of local anesthetic,[148] and vital parameters, techniques, and doses of local anesthetics must be reported on a detailed anesthesia chart. It is also imperative to site mark the area to be blocked and get consent, if under 10 years, and consent and assent from the patient, if they are older.

Technique of Injection

Techniques in adults and children are similar. Of prime importance is to evaluate the effects on ECG tracings of a test dose containing epinephrine (0.1 mL/kg up to 3 mL containing 0.5-1 μg/kg of epinephrine) for 30 to 60 seconds. Any elevation of ST segment or increase in T-wave amplitude,[149-151] followed by an increase in blood pressure but only occasionally by tachycardia, suggests inadvertent intravenous injection and necessitates cessation of the procedure; when epinephrine is contraindicated, isoproterenol 0.05 to 0.1 μg/kg should be used instead.[152]

Assessment of the Block

After every block procedure, the quality and extension of analgesia must be evaluated before surgical incision. However, this evaluation is difficult, even in conscious children. Gentle skin pinching is the most dependable technique of sensory testing, especially in lightly anesthetized children. One technique is to use ice in a plastic bag to determine the efficacy of the block in lightly sedated children; however, it may be difficult to elicit any response in children under general anesthesia. Electrical stimulation using a nerve stimulator at different threshold intensities proved to be suitable in healthy volunteers, but data on children are limited. Skin temperature is not suitable, and whether pupillary reflex dilation of 0.2 mm is sensitive to the loss of analgesia is not clinically useful.[153]

POSTOPERATIVE MONITORING IN THE RECOVERY ROOM

After combined regional and general anesthesia, all children must be transferred to a recovery room (PACU), where the stability of respiratory and hemodynamic status is checked in the same way as after any general anesthesia. In addition to this standard postanesthetic care, they require repeat evaluations of the anesthetized area. In the case of motor blockade, which should be avoided as often as possible, it is important to verify that its distribution corresponds to the area supplied to the blocked nerve. Patient positioning must be carefully and regularly checked to avoid pressure points. The possibility that a compartment syndrome is evolving must always be kept in mind, and both the hemodynamic status of the relevant limb and the quality of analgesia must be repeatedly evaluated.

Urinary retention can be of concern after neuraxial blocks. In many institutions, however, voiding is not requested before discharging the child.

Adult surgical patients under regional blockade often bypass the postanesthesia recovery room. In children, even if no sedative has been given, it is not wise to do so, and adequate monitoring and skilled assistance improve recovery from immediate postoperative incidents.[154] After short procedures, sudden cessation of external stimulation may unmask some compensated adverse effects (hemodynamic and respiratory especially) that are not harmful if detected early. As noted earlier, ropivacaine and, to a lesser extent, levobupivacaine, have a longer T_{max} (up to 2 hours) and C_{max} in infants; therefore after short-duration surgeries, these patients may leave the operating room before local anesthetic plasma peak concentration has been reached. It is recommended to keep them monitored in a PACU up to 2 hours after the block procedure.

DISCHARGE CRITERIA AFTER SINGLE-SHOT PROCEDURES

The same criteria apply with discharge from the PACU as with after general anesthesia (pediatric adaptation of Aldrete score or specific scoring method in use in the relevant institution); in the absence of motor blockade, children usually may be discharged within 30 minutes. In other cases, discharge depends on the behavior of the child. Partial restoration of motor function is mandatory, even in quiet children with caring families. Boisterous children should not leave before motor functions have been fully restored; additionally, protective dressings (including casts) may help prevent harm to the operated limb. Persistence of sensory blockade is not a contraindication to early discharge unless the familial environment is inadequate. Pain medication should be systematically prescribed and administered on a regular basis to prevent the return of intense pain at home when the sensory block is no longer effective.[155] Most additives do not preclude early discharge except for epidural or intrathecal opioids, especially morphine, or hydromorphone which necessitates that the child stay hospitalized overnight.

MANAGEMENT OF CONTINUOUS REGIONAL TECHNIQUES

Children with patient controlled or continuous epidural infusion should remain hospitalized to be adequately monitored. Occasionally, a few selected patients can be allowed to return home with an epidural catheter, mostly in a context of chronic pain or cancer pain in terminally ill children. These continuous techniques are newer in pediatrics[74] and not yet widely used. Studies on peripheral nerve blocks in children monitored at home have reported a low complication rate and good quality of analgesia.[156,157] In one institution, children suffering from CRPS were treated at home with peripheral nerve catheters.[80] The use of an elastomeric disposable device to infuse local anesthetic allows simplifying the management of children at home and a nursing economy. Such management will probably gain wider acceptance in the near future, but currently it should be considered under evaluation.

Neuraxial Blocks

CAUDAL ANESTHESIA

Ultrasound Guidance for Caudal Block Placement

- Initially use a transverse plane of imaging to identify the sacral hiatus located between the cornua; the sacral hiatus is located between an upper hyperechoic line representing the sacrococcygeal membrane/ligament and an inferior hyperechoic line representing the dorsum of the pelvic surface (base) of the sacrum.

- Rotate the probe to the longitudinal plane (a paramedian plane may be required in older children) to capture the sacrococcygeal membrane, a relatively thick linear hyperechoic band, sloping caudally.
- Insert the needle under either plane of view, although a longitudinal view may allow for optimal viewing along the needle. A transverse view can be used after needle placement within the epidural space, in order to view the spread of local anesthetic (as dilation of the caudal space and localized turbulence).

The caudal block is likely the most commonly used technique of central neuraxial blockade in children. Nevertheless, it is less used in some countries in favor of peripheral blocks due to the use of ultrasound guidance.[99] The technique is described as simple and easy to perform for most, with few complications.

Caudal anesthesia considerably decreases stress hormone response to surgery.[158-160] The rate of complete or partial failure of this technique is 3% to 11%,[161] especially in children older than 7 years of age.

Anatomy of the Sacral Hiatus

Children have a specific anatomic level of the sacrum. Until the age of 1 year, five sacral vertebrae are easily identifiable and have the appearance of the lumbar vertebrae. Each sacral vertebra has five primitive centers of ossification, which will knit by 2 to 6 years of age. This is due to the standing body of the child, who will develop the walking and the mechanical stresses in the vertebrae.

The sacral hiatus is a U-shaped or V-shaped aperture resulting from the lack of dorsal fusion of the fifth and often fourth sacral vertebral arches. It is limited laterally by two palpable bony structures, the sacral cornua, and is covered by the sacrococcygeal membrane (sacral continuation of the ligamenta flava). The distance separating the summit of the sacral hiatus and the dural sac ending is approximately 30 mm (SD=10 mm) (range, 13.6-54.7 mm) in children 10 months to 18 years of age.[162] Mean distance from skin to anterior sacral wall is 21 mm (extremes, 10-39 mm) between 2 months and 7 years of age.[142] The distance from skin to the epidural space is only slightly influenced by the age and weight of the patient (Fig. 76.1), and 25-mm needles are long enough to reach the sacral epidural space and short enough to prevent inadvertent dural puncture in most patients.

With growth, the axis of sacrum changes; the sacral hiatus becomes more difficult to identify and may even close.[163] Concomitantly, the epidural fat becomes more densely packed, thus reducing the spread of local anesthetics. These changes make caudal anesthesia less suitable and more difficult to perform in children older than 6 to 7 years of age.

Indications, Contraindications, and Complications. Caudal anesthesia is recommended for most surgical procedures of the lower part of the body (mainly below the umbilicus), including inguinal hernia repair, urinary and digestive tract surgery, and orthopedic procedures on the pelvic girdle and lower extremities.[164] It is usually performed in lightly anesthetized patients but can be used as the sole anesthetic regimen in fully awake former premature infants younger than 50 to 60 weeks of postconceptual age after local anesthesia of the skin covering the sacral hiatus, either as a single-shot technique[165,166] or after placement of an epidural catheter allowing repeat or continuous injection of local anesthetics.[167]

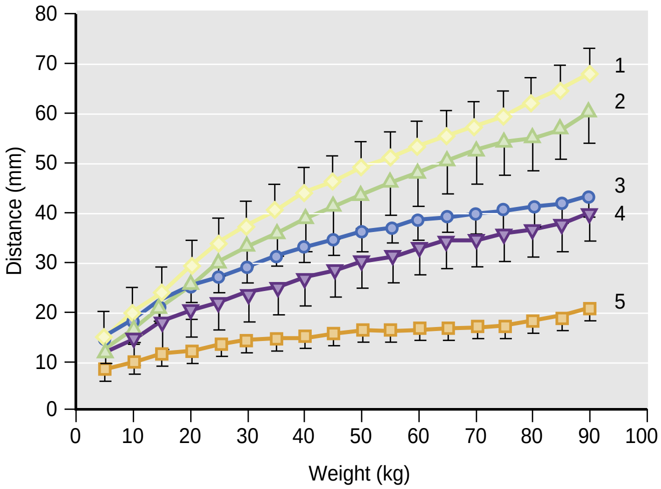

Fig. 76.1 Distance from the skin to the epidural and subarachnoid spaces at different intervertebral levels and through the sacral hiatus. *1,* Spinal anesthesia; *2,* lumbar epidural approach (midline); *3,* thoracic epidural approach (midline); *4,* sacral epidural approach; *5,* caudal approach.

Contraindications include major malformations of the sacrum (myelomeningocele, open spina bifida), meningitis, and intracranial hypertension.

Complications of caudal anesthesia are infrequent and usually minor[92,99] when adequate devices are used. Notably, dural puncture and subsequent injection of local anesthetic solution can lead to cardiovascular collapse or respiratory arrest (apnea). A large database of 18,650 caudal blocks registry demonstrated an overall rate of complications of 1.9%, with no temporary or permanent sequelae; an estimated incidence of 0.005%, further suggesting safety concerns, should not be a barrier to the use of caudal blocks in children.[168]

Technique

The technique is performed with the patient in the lateral decubitus position or, especially in awake premature infants, in the prone position either with a rolled towel slipped under the pelvis or with the legs flexed in the “frog” position. The two sacral cornua limiting the V-shaped sacral hiatus are located by palpation along the spinal process line at the level of the sacrococcygeal joint (Fig. 76.2). The hiatus along with the two posterior superior iliac crests is claimed to form an equilateral triangle, but in clinical practice this assumption does not help in locating the hiatus when palpation is not informative. The caudal puncture technique is shown in Fig. 76.3.

Caudal anesthesia is basically a single-shot technique. Occasionally, placement of an epidural catheter for repeat or continuous infusion is contemplated. The “normal” length of catheter to be introduced into the epidural space is 2 to 3 cm, as for any epidural block. Because the epidural fat is very fluid in infants, a longer distance can be introduced to reach lumbar or even thoracic levels. This technique should be considered with caution, by experts only. The final position of the tip of the catheter must be controlled; it is misplaced in 28% of cases.[169] This is usually achieved by obtaining a contrast-enhanced radiograph, but the following techniques also are available:

- Nerve stimulation at rather high intensities (however, safety of this technique is not established).[170,171]
- Recording ECG tracings from the metallic wire of the catheter and comparing them with those obtained from an electrode placed on the spinous process line, at the level where the tip of the catheter should be placed. The position is correct when the two tracings are identical.[172] This technique is very elegant and noninvasive, but the "second" ECG tracing is not easily readable in some patients (especially when they are conscious and moving).
- Ultrasound guidance[173] is the most promising noninvasive technique.

Catheter tunneling has been recommended to decrease the risk for bacterial contamination.[174] The volume prescription scheme of Armitage that was published many years ago still remains the most dependable, as follows:

- 0.5 mL/kg: All sacral dermatomes are blocked.
- 1 mL/kg: All sacral and lumbar dermatomes are blocked.
- 1.25 mL/kg: The upper limit of anesthesia is at least midthoracic.

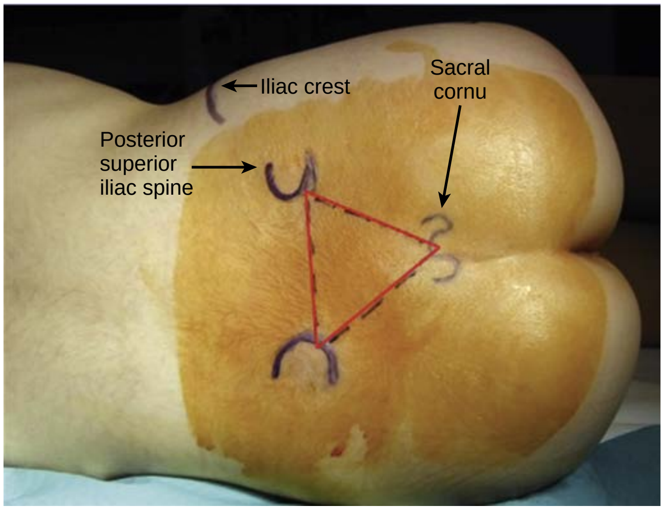

Fig. 76.2 Landmarks for caudal block procedure in lateral position. Two posterior superior iliac crests form an equilateral triangle; the top of this triangle indicates V-shaped sacral hiatus limited by two sacral cornua.

When 1.25 mL/kg is injected, excessive rostral spread (above T4) can occur[175]; it is therefore preferable not to administer more than 1 mL/kg of local anesthetic. Hong and colleagues[176] sought the best compromise between the two regimens of caudal injections in terms of quality of analgesia and spread of local anesthetic. The authors compared the same total dose of local anesthetic (ropivacaine 2.25 mg/kg), a high injection volume and low concentration (ropivacaine 0.15% 1.5 mL/kg), and low injection volume and high concentration (ropivacaine 0.225% 1 mL/kg). Spread of local anesthetic was significantly higher in the high volume and low concentration group in contrast to the other group (T6 [T3-T11] and T11 [T8-L2], respectively). In addition to the injection system, high volume and low concentration produced a longer duration of analgesia before the first analgesic request (554.5 minutes vs. 363 minutes). When a catheter is inserted, repeat injections must be reduced to avoid systemic toxicity. The second injection should be made no earlier than 60 minutes (for a short-duration local anesthetic) or 90 minutes (for a long-duration local anesthetic) after the first one and should be half of the initial dose. Further injections should be reduced to half of the second dose (i.e., one sixth of the initial dose) while respecting the same delays.

Ultrasound has facilitated the use of caudal block in children, allowing an initial assessment of the anatomy of the sacrum (Fig. 76.4), including the relationship of the sacral hiatus to the dural sac ending, and research of spinal dysraphism.[143] Roberts and associates[173] demonstrated the value of ultrasound imaging with a test dose of saline when performing a caudal block to confirm the correct location of the needle. According to the authors, the displacement of the dura mater during the injection of saline is an indicator of a successful block. They found ultrasound-guided caudal blocks successful with a sensitivity of 96.5%, a specificity of 100%, and a positive predictive value 100%. Ultrasound is also better than the swoosh test to determine the correct location of the needle.[177] Recently, Shin and associates[178] noted that prior anatomic study of the sacral region via ultrasound made it easier to identify the sacral hiatus and determine the level of the dural sac before completion of a caudal block or block-sacral interspinous in children.

EPIDURAL ANESTHESIA

EPIDURAL ANALGESIA UNDER ULTRASOUND GUIDANCE

- Ultrasound-guided technique does not preclude continuous testing for loss of resistance.
- The limitation of the technique is that the needle shaft and tip may be hard to localize with the tangential relationship of the needle (midline) and the probe (paramedian longitudinal).
- An assistant (second set of hands) is required during catheter placement in order to perform the imaging real-time for ultrasound-aided catheter placement. It is important to use saline for the loss of resistance technique to facilitate ultrasound imaging.

Anatomy and Physiology

The epidural space surrounds the spinal cord and the meninges from the foramen magnum to the sacral hiatus. Limited posteriorly by the vertebral laminae and the ligamenta flava, it communicates quite freely with both the paravertebral spaces and the root sleeves. In the dural cuff region, near the spinal ganglia, it is intimately connected with the subarachnoid space owing to protrusion of arachnoid granulations, which are easily traversed by local anesthetics. It contains blood vessels and lymphatics and is filled with loose fat in infants and in children up to 6 to 8 years of age.

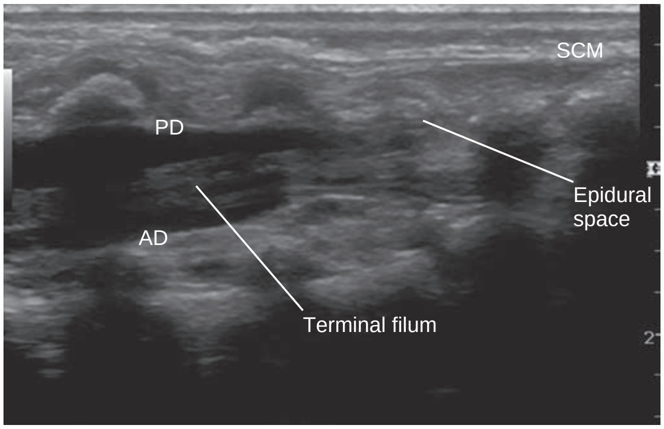

Fig. 76.4 Ultrasound-guided caudal block facilitating initial assessment of the anatomy of the sacrum. *AD,* Anterior dura mater; *PD,* posterior dura mater; *SCM,* sacrococcygeal membrane.

One of the major characteristics of the child for the central blocks is a line connecting the two iliac crests—the Tuffier line. This line joining the two iliac crests is proportionally smaller in young children and crosses the spinous process line at the L5 to S1 level in infants up to 1 year of age instead of at L4 to L5 as in older children and adults.[179] Bending the spine (as for performing an epidural block) does change the level at which the Tuffier line crosses the spine in 58.3% of patients. Mobility of the vertebrae and the elasticity of the ligaments in children can change the position of the spinal cord in the spinal canal. The spinal cord tends to move backward and get closer to the vertebral arches in a sitting position, making it more difficult to identify the epidural space. In the lateral decubitus position, bending moves the spinal cord forward, away from the ligamentum flavum and expands the epidural space. This is the preferred position for the epidural catheter procedure in children (Fig. 76.5).

Epidural injections result in considerable pressure changes. After placement of a 20-gauge epidural catheter in 20 infants, Vas and associates[180] measured the following changes:

- Pressure on penetrating the epidural space: 1 ± 10 mm Hg (extremes, −17 to +16 mm Hg)
- Peak pressure during injection of a local anesthetic at 1 mL/min: 27.8 ± 18.6 mm Hg with residual pressure of 12 ± 5.5 mm Hg 1 minute after completion of injection
- Peak pressure during injection of a local anesthetic at 0.5 mL/min: 15.2 ± 9.5 mm Hg with residual pressure of 14.8 ± 5.4 mm Hg 1 minute after completion of injection

The spine presents at birth only one concavity: anterior curvature (kyphosis). Lumbar lordosis appears only with the acquisition of walking. Until the installation of lordosis, the spinous processes are parallel and the introduction of the needle between them in the epidural space is perpendicular to the plane of the back. In addition, ossification of the lumbar vertebrae is very underdeveloped at birth and risks exist for injury to cartilaginous structures.

Indications and Contraindications

Young children tolerate epidural anesthesia well without significant hemodynamic changes.[56] Epidural anesthesia

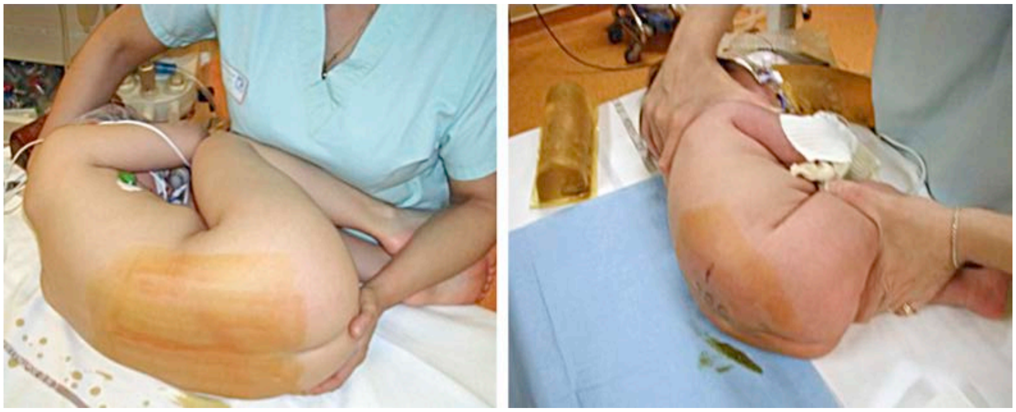

Fig. 76.5 Lateral position for epidural puncture in a 10-year-old boy *(left)* and 4-month-old girl *(right)*.

is recommended for all major abdominal, retroperitoneal, pelvic, and thoracic[181,182] procedures, including pectus excavatum repair[183] and scoliosis surgery,[184,185] preferably with a two-catheter technique.[69] The technique is also used for cardiac surgery in a few institutions,[70,186] but this indication is controversial and most authors consider it contraindicated because of anticoagulation.

The intervertebral level at which the epidural space should be approached is a matter of debate and depends on both the patient's age and the experience of the anesthesiologist. When a single-shot technique is planned for a surgery below the umbilicus, a caudal approach is most often selected in infants and young children and a lumbar approach is used in older patients. When catheter placement is contemplated it is preferable to select a lumbar approach in all patients to decrease the risk for bacterial contamination from anal proximity, even though this is rare.[92]

When sensory blockade of high thoracic dermatomes is required, the most reliable approach is a thoracic epidural block, which requires expertise because the spinal cord could be damaged. When the anesthesiologist is not used to performing thoracic epidural blocks in infants, some authors recommend a caudal approach with cephalic insertion of a catheter over a long distance to reach thoracic levels.[187] This technique, however, requires experience and luck—the catheter is misplaced in almost 30% of cases, even in experienced hands,[169] and serious complications are possible (e.g., spinal cord or vessel trauma during insertion, bacterial contamination, breakage, or buckling around a nerve root on removal attempts).[188-190]

Specific contraindications to epidural anesthesia include severe malformations of the spine and spinal cord (not spina bifida occulta), intraspinal lesions or tumors, and tethered cord syndrome. In most instances, epidural anesthesia should be avoided in children with a history of hydrocephalus, elevated intracranial pressure, unstable epilepsy, or reduced intracranial compliance, but these disorders are not absolute contraindications, depending on the context.[191] Also, previous surgery on the spine usually makes epidural (and spinal) anesthesia technically difficult or impossible, but they are not contraindications unless underlying lesions of the spinal cord are present.

Techniques

Lumbar Epidural Anesthesia. The lumbar epidural is usually performed in anesthetized patients via a midline route below the L2 to L3 interspace, which represents the lower limit of the conus medullaris (Fig. 76.6). The technique is essentially as in adults. A paramedian approach can be used instead in cases of spinous process anomaly or spine deformity. The child is positioned in the semiprone position, with the side to be operated lowermost and the spine bent to enlarge the interspinous spaces. The sitting position can be used in conscious patients.

Medium selection for the LOR technique has elicited considerable debate. Both air and saline are advocated for the LOR test to identify the epidural space. Saline is more popular, however air (or carbon dioxide) is perhaps more sensitive, especially in neonates and infants.

The distance from the skin to the epidural space is correlated with the patient's age and size (see Fig. 76.1), but 1 mm/kg is a useful approximation for children between 6 months and 10 years of age.[192] An ultrasound probe provides precise measurement of the distance from skin to the ligamenta flava and from skin to the posterior dura mater (Fig. 76.7).

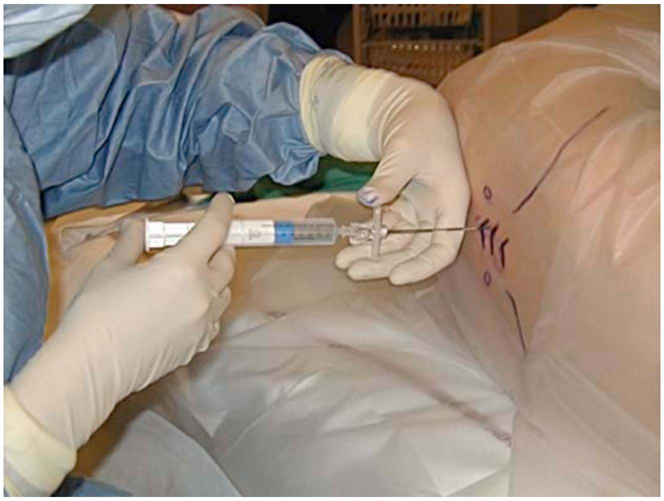

Fig. 76.6 Lumbar epidural anesthesia by loss-of-resistance technique with saline.

When the tip of the needle penetrates the epidural space, the LOR technique syringe is disconnected, and no reflux of biologic fluid (blood or CSF) should appear at the hub. The next step consists of injecting the local anesthetic at a slow speed, either through the epidural needle or through a catheter. Progressive displacement of the dura mater can be visualized by placing an ultrasound probe in line with the spinous process line during injection in infants younger than 2 years of age.[145] By using ultrasound, the anatomy of the spinal canal, the position of the spinal cord, visualization of the ligamentum flavum, and the space caudal spinous processes can actually be seen (see Fig. 76.7).[193] When a catheter is inserted, it should not be introduced more than 3 cm, to avoid buckling, knotting, and lateralization of blockade or erratic migration. Tunneling the catheter reduces the incidence of accidental removal and bacterial contamination.[194] Catheters inserted over a long distance have to be controlled in the same way as caudal catheters.

The volume of anesthetic solution depends on the upper level of analgesia required for completion of the surgery; approximately 0.1 mL/year of age is necessary to block 1 neuromere.[195] Usual volumes of injectate range from 0.5 to 1 mL/kg (up to 20 mL), and the upper limit of sensory blockade ranges between T9 and T6 in more than 80% of patients.

Single-shot epidural blocks are appropriate for many pediatric surgeries, especially when adjuvants such as clonidine 1 to 2 μg/kg, and, in appropriate indications, morphine 30 μg/kg, or 10 μg /kg of hydromorphone are coadministered. Major operations resulting in long-lasting postoperative pain require placement of an epidural catheter and postoperative infusion of local anesthetics (Table 76.8).

In mature children who understand the concept of patient-controlled analgesia and who are willing to use it, patient-controlled epidural analgesia (PCEA) can be an interesting option. A prospective study involving 128 children older than 5 years of age reported a 90.1%

success rate; PCEA was stopped in 6.1% of children because of adverse effects and only in 3.8% because of inadequate analgesia.[196] The local anesthetic was either 0.0625% or 0.125% bupivacaine with fentanyl 2 to 10 μg/mL; the background infusion rate was 0.2 mL/kg/h or less, and 1- to 3-mL bolus doses were permitted every 15 to 30 minutes with a maximum dose of bupivacaine of 0.4 mg/kg/h.

Another prospective study involving 58 children (age range, 7-12 years) undergoing lower extremity orthopedic surgery compared continuous epidural infusion of 0.2% ropivacaine 0.2 mL/kg/h with PCEA, with background infusion of 1.6 mL/h and 2-mL bolus doses (lockout interval, 10 minutes) of the same solution. Pain scores were excellent and identical in both groups, but children from the PCEA group required half the doses of ropivacaine on an hourly basis in contrast to the continuous infusion group.[123]

Thoracic Epidural Anesthesia. Thoracic epidural blocks are indicated for major operations requiring long-lasting pain relief, thus requiring placement of an epidural catheter to allow repeat injections or continuous infusion of local anesthetic. These are not commonly used techniques in children because indications are limited to thoracic and upper abdominal surgery and spinal cord damage is a risk. In children younger than 1 year of age, the procedure is similar to that for a lumbar approach, with needle insertion perpendicular to the spinous process line, because the spine displays a single flexure, especially when bent. As the patient grows and the flexure develops, the technique becomes progressively similar to thoracic approaches in adults, requiring cephalic orientation of the Tuohy needle up to a 45-degree angle to the skin. A paramedian approach can be used instead, but it is rarely required in children. In infants, ultrasonography makes visible the dura mater, the progression of the Tuohy needle, and, in many cases, the progression and final position of the tip of the epidural catheter.[197]

TABLE 76.8 Usual Doses and Infusion Regimens for Epidural Anesthesia in Pediatric Patients

Agent	Initial Dose	Continuous Infusion (Maximum Doses)	Repeat Injections
Bupivacaine, levobupivacaine	Solution: 0.25% with 5 μg/mL (1/200,000) epinephrine Dose: <20 kg: 0.75 mL/kg 20-40 kg: 8-10 mL (or 0.1 mL/year/no. of metameres) >40 kg: same as for adults	<4 months: 0.2 mg/kg/h (0.15 mL/kg/h of a 0.125% solution or 0.3 mL/kg/h of a 0.0625% solution) 4-18 months: 0.25 mg/kg/h (0.2 mL/kg/h of a 0.125% solution or 0.4 mL/kg/h of a 0.0625% solution) >18 months: 0.3-0.375 mg/kg/h (0.3 mL/kg/h of a 0.125% solution or 0.6 mL/kg/h of a 0.0625% solution)	0.1-0.3 mL/kg every 6-12 h of a 0.25% or 0.125% solution (according to pain scores)
Ropivacaine	Solution: 0.2% Dose: Same regimen in mL/kg as for bupivacaine (see above)	Same age-related infusion rates in mg/kg/h as for bupivacaine (usual concentration of ropivacaine: 0.1%, 0.15%, or 0.2%) Do not infuse for more than 36 h in infants <3 months	0.1-0.3 mL/kg every 6-12 h of a 0.15% or 0.2% solution (according to pain scores)
Adjuvants	Avoid in infants <6 months Fentanyl 1-2 μg/kg or sufentanil 0.1-0.6 μg/kg or clonidine 1-2 μg/kg	Select only one additive: Fentanyl: 1-2 μg/mL Sufentanil: 0.25-0.5 μg/mL Morphine: 10 μg/mL Hydromorphone: 1-3 μg/mL Clonidine 0.3 at 1 μg/mL of solution	Morphine (without preservatives): 25-30 μg/kg every 8 h

Cervical Epidural Anesthesia. No surgical indications exist for cervical epidural blockade in children. Very rarely, the technique can be contemplated for patients with chronic pain or to prevent phantom limb pain before an amputation of the upper arm at the scapular level (osteosarcoma of humerus), which is done almost exclusively in adolescents. The block procedure is the same as in adults.

SPINAL ANESTHESIA

Anatomy and Physiology

The spinal cord and dural sac of infants younger than 1 year of age end at a lower level than in older patients (see earlier section on Caudal Anesthesia). Also, the volume of CSF varies considerably according to the patient's age, from more than 10 mL/kg in neonates, to 4 mL/kg in infants weighing less than 15 kg, to 3 mL/kg in children, to 1.5 to 2.0 mL/kg in adolescents and adults. The spinal and cerebral distribution of CSF also varies with age; half the CSF volume is located within the spinal subarachnoid space versus only 25% in adults. This has considerable pharmacokinetic consequences and explains why larger doses of local anesthetics are required for spinal anesthesia in infants and young children.

CSF hydrostatic pressure is lower in infants in the dorsal recumbent position[198] and further decreased during general anesthesia. In performing a spinal block, the progression of the needle must be slow to detect CSF reflux before the needle is advanced farther.

Children older than 5 years of age behave like adults after spinal anesthesia, whereas younger patients remain hemodynamically stable, without significant hypotension or bradycardia,[199] even in cases of cardiac malformations.[200] However, a decrease in mean arterial pressure during the first 10 minutes after injection of 0.8 mg/kg of 0.5% bupivacaine was reported in infants aged 1.5 to 5 months.[201] This decrease was time limited, well tolerated, and rapidly corrected by intravenous fluids. Similar results with concomitant decrease in cerebral blood flow were reported in former preterm infants of 41 weeks of postconceptual age.[202]

Indications and Contraindications

Spinal anesthesia has limited indications in pediatric patients. One of these is inguinal hernia repair in former preterm infants younger than 60 weeks of postconceptual age[203,204] who are prone to develop postoperative apnea after general anesthesia or even light sedation.[205] However, even after pure spinal anesthesia, apnea may occur postoperatively (as they may preoperatively) and it is prudent to keep at-risk infants hospitalized. Other indications are scarce, mainly for elective lower abdominal or lower extremity surgery[206-208] and, occasionally, for cardiac surgery or cardiac catheterization,[209,210] but these indications are controversial. There has been a greater increase in interest in spinal anesthetics for infants lately due to the potential for neurocognitive changes associated with general anesthesia.[211-213]

Technique

The technique of spinal anesthesia is similar to lumbar puncture (Fig. 76.8). It can be performed with the patient in the lateral decubitus position or sitting (Fig. 76.9). Currently, hyperbaric tetracaine and bupivacaine are the most commonly used local anesthetics. Isobaric bupivacaine can be used instead.[206] Ropivacaine[208] and levobupivacaine[214] may become the standard of the future but are not currently approved for spinal administration in pediatric patients.

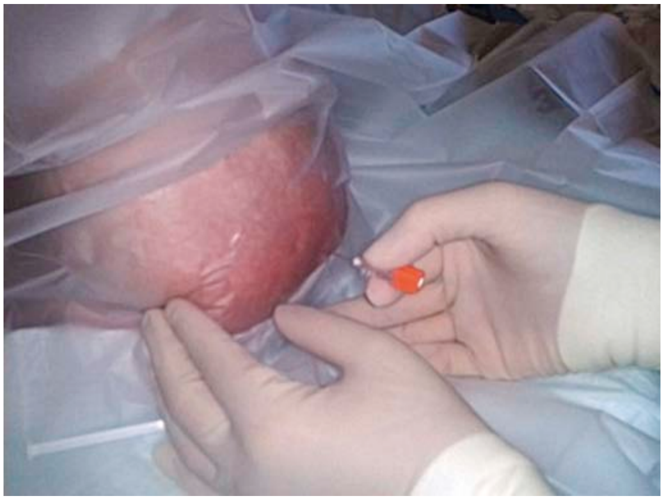

Fig. 76.8 Spinal anesthesia procedure in sitting position in 1-month-old girl.

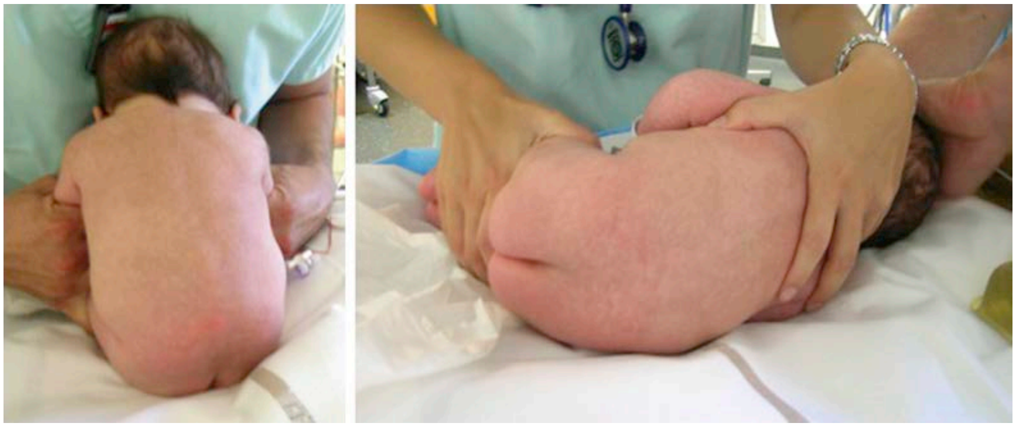

Fig. 76.9 Sitting or lateral position for spinal anesthesia procedure.

Drugs and Doses

The drugs most frequently used are tetracaine 0.5% and bupivacaine 0.5%. The usual doses are 0.5 to 0.8 mg/kg to achieve low to medium levels and 1 mg/kg to achieve high levels (T2-T4). The duration of the block is approximately 60 to 75 minutes for both drugs. Newborns and infants are at an increased risk for toxicity after the administration of amide local anesthetics; the risk is even greater in the case of jaundice.[215] Usual dosages for neonates to adolescents are given in Table 76.9.

The older the child, the lower is the dose required; in children between 6 months and 14 years, 0.5% hyperbaric bupivacaine at a dose of 0.2 mg/kg has been used with a success rate of 98%. More recently, the successful use of 0.5% ropivacaine in children between 1 and 17 years at 0.5 mg/kg and 0.5% levobupivacaine in children between 1 and 14 years at 0.3 mg/kg has been reported. Clonidine 1 µg/kg, fentanyl 1 µg/kg, and morphine 4 to 5 µg/kg are reported in the pediatric literature as adjuvants to increase the spinal block duration (see Table 76.9). In cardiac patients, a higher dose of morphine has been used for spinal anesthesia to ensure adequate postoperative analgesia.

Adverse Effects and Complications

Spinal anesthesia is technically difficult in neonates and infants; the overall failure rate ranges from 10% to 25%.[205,216] Short duration of blockade and lack of residual analgesia are important limitations, and alternative (awake caudal anesthesia) or additional techniques (ilioinguinal or iliohypogastric block) are often contemplated. Postdural puncture headache is rare in children younger than 8 years of age but not exceptional, and its incidence may be decreased with use of pencil-point spinal needles.[217] All complications reported after lumbar epidural blockade can occur after spinal anesthesia.

Upper Extremity Conduction Blocks

ANATOMIC CONSIDERATIONS

Nerve supply to the upper extremity depends mainly on the brachial plexus formed by the union of the ventral rami of the fifth cervical to the first thoracic spinal nerve roots. Roots emerge from the intervertebral foramina within the interscalene space (between the scalene anterior and scalene middle muscle). As in adults, brachial plexus nerve fibers redistribute first to three trunks (superior, middle, and inferior), then to three divisions between the clavicle and the first rib. These divisions recombine and surround the axillary artery as three cords and are named according to their relation to the artery as the lateral, medial, and posterior cords (Fig. 76.10). Because of this complicated redistribution of nerve fibers, distribution of anesthesia varies considerably depending on the level at which the local anesthetic is injected. Some anatomic knowledge is essential to predict the extension of the motor and sensory block and to determine the most appropriate approach for a given surgery (Fig. 76.11).

TABLE 76.9 Usual Doses of Local Anesthetics for Spinal Anesthesia

Local Anesthetic	Dose	Duration
NEONATES		
Tetracaine 0.5%	0.6-1 mg/kg	60-75 min
Bupivacaine 0.5%	0.5-1 mg/kg	65-75 min
Ropivacaine 0.5%	1.08 mg/kg	50-70 min
Levobupivacaine 0.5%	1 mg/kg	75-90 min
INFANTS TO ADOLESCENT		
Bupivacaine 0.5%	0.4 mg/kg (5-15 kg)	
Tetracaine 0.5%	0.3 mg/kg (<15 kg)	
Levobupivacaine 0.5%	0.4 mg/kg (5-15 kg)	
Ropivacaine 0.5%	0.3 mg/kg (>15 kg)	
	0.4 mg/kg (5-15 kg)	
	0.3 mg/kg (15-40 kg)	
	0.25 mg/kg (>40 kg)	
	0.5 mg/kg (maximum 20 mg)	
ADJUVANT		
Clonidine	1 µg/kg (neonates)	
Fentanyl	1 µg/kg (infants <1 year)	
Morphine	4-5 µg/kg (all ages)	

The most important anatomic difference between infants and adults pertains to the upper part of the lung and apical pleura that penetrates the neck, above the plane formed by the clavicle and first rib (superior thoracic aperture). Subclavian vessels and the lower division of the plexus are encountered in the apical pleura, thus making any perisubclavian approach at major risk for pleural penetration. The concept of perineurovascular sheath has been challenged in spite of strong embryologic and anatomic evidence, but it received additional confirmation in a recent radiologic study, and even the volume of the axillary tunnel could be precisely measured (5.1-9.5 mL in adults).[218]

Ultrasound imaging allows precise localization of the parietal pleura and subclavian and axillary vessels, thus improving the safety of supraclavicular and infraclavicular approaches, provided the tip of the block needle can be continuously seen during the procedure. Nerve stimulation may be used in conjunction with ultrasound guidance to confirm the localized nerve and prevent an intraneural injection.

Roberts[139] recommended initially performing simple blocks. Interscalene and periclavicular approaches are considered difficult and must be done by trained operators. The axillary and forearm blocks seem easier, especially for those who are new to ultrasound-guided regional anesthesia.

Indications for brachial plexus blocks include emergency and elective surgery of the upper extremity in conscious or anesthetized children.[219–221] These blocks are useful for outpatient surgery and elicit a high degree of patient satisfaction.

- The axillary block was the most common approach to the brachial plexus in pediatric patients, especially when the lesions involve the forearm and the hand. Advantages of this block include an easy and safe procedure with a high rate of success and very low rate of complications. With the advent of ultrasonographic guidance, the supraclavicular block seems to be the most common block for upper extremity in children.[114]

- The infraclavicular paracoracoid approach is being increasingly used with the development of ultrasound guidance. The technique provides complete blockade of the upper extremity, catheter placement is easier and more comfortable than at axillary levels, and catheter immobilization and protection against accidental removal are also easier.
- Supraclavicular approaches are indicated when the lesion is located on the shoulder or on the proximal part of the arm, including the elbow. This approach should be used in infants with extreme caution because of the proximity of the apical pleura; ultrasound imaging reduces the risk for complications such as vascular or pleural incidental punctures. Before the use of

ultrasound-guided nerve block, the parascalene and the modified interscalene approach (the tip of the block needle is placed virtually at the same place in the interscalene space with both techniques) were considered as safe alternative procedures.

- Distal nerve blocks are used either for distal lesions (surgery involving the hand or one finger only) or as complementary block when distribution of anesthesia is incomplete after a more proximal block.

CERVICAL BRACHIAL PLEXUS BLOCKS

Cervical brachial plexus approaches are not commonly used in children because of potential adverse effects (pneumothorax, vertebral artery injection, intrathecal injection) and the low incidence of isolated shoulder surgery in this population.

Interscalene Approach

The interscalene approach aims to enter the interscalene space at its upper extremity, close to the transverse process of C6. The child is placed in the dorsal recumbent position with the arms extended alongside the thorax and head slightly turned to the contralateral side.

The landmarks are the cricoid cartilage, the anterior ramus of the C6 transverse process (Chassaignac tubercle), and the interscalene groove. The puncture site is located at the skin projection of Chassaignac tubercle in the interscalene groove, just posterior to the lateral border of the sternocleidomastoid muscle. The needle is inserted at an 80-degree angle (not perpendicularly) to the skin; that is, dorsally and slightly caudal pointing toward the midpoint of the clavicle, until one of the primary trunks (instead of roots) of the brachial plexus is located by elicited muscle twitches in the upper arm. Any distal motor twitch and biceps, triceps, or deltoid muscles are adequate (Fig. 76.12). Contraction of the diaphragm indicates phrenic nerve stimulation and anterior placement of the needle tip. Alternatively, trapezius muscle stimulation indicates that needle placement is too posterior. Borgeat and colleagues[222] described a modified technique in adults that can be used in children. The block needle is inserted at the same puncture site, but the needle is oriented laterally, pointing toward the midpoint of the clavicle until one of the primary trunks (instead of roots) of the brachial plexus is located and twitches are elicited in the upper arm. The interscalene block is not very popular in children because of its adverse effects—ipsilateral phrenic nerve blockade, danger of vascular damage (vertebral artery and vein), and accidental cervical epidural and intrathecal penetration.

Ultrasound imaging improves the safety of this approach by showing the great vessels of the neck, aponeuroses of scalene muscles, and C5-C6-C7 brachial plexus roots.[138,223] The probe is placed in a transverse oblique plane at the level of the cricoid cartilage (Fig. 76.13). The trunks and roots of the brachial plexus can be identified in the interscalene groove as distinct round-to-oval hypoechoic structures between the scalene anterior and middle muscles, both deep to the sternocleidomastoid muscle. The internal jugular vein and carotid artery can be visualized medially (Fig. 76.14). Using combined ultrasound-guided nerve stimulation techniques, the needle is advanced with an in-plane alignment from lateral (posterior) to medial (anterior) side of the probe, toward the target nerves. Precise needle placement may limit the dose of local anesthetic required.[224]

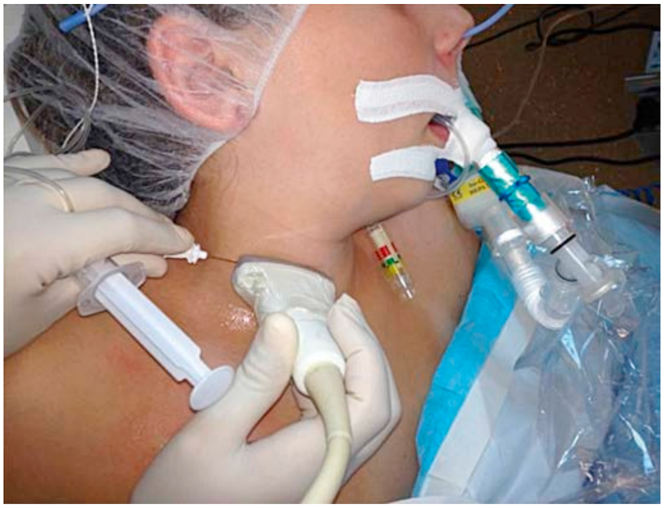

Fig. 76.13 Ultrasound interscalene block procedure: patient head and probe position and in-plane needle approach.

Parascalene Approach

The parascalene approach described by Dalens and colleagues[225] aims to penetrate the interscalene space at a distance from the apical pleura and great vessels of the neck. The landmarks are the midpoint of the upper border of the clavicle and the transverse process of C6 located by palpation in the interscalene groove, just posterior to the sternocleidomastoid muscle, at the level of the cricoid cartilage. The puncture site is identified at the junction of the upper two thirds, with the lower third of the line joining the skin projection of the C6 process and the midpoint of the clavicle (Fig. 76.15). The success rate for this approach is very

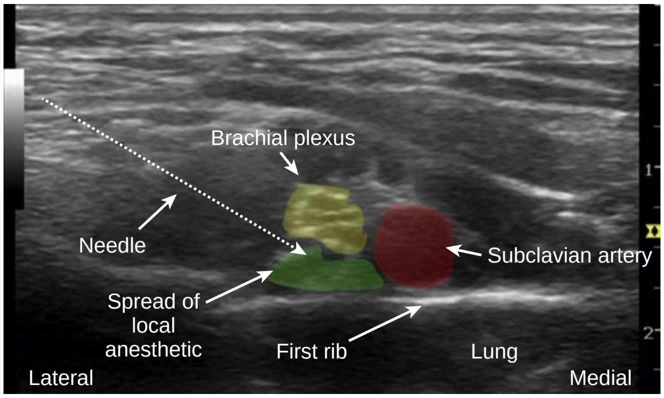

Fig. 76.17 Ultrasound supraclavicular block imaging.

high, with a good safety record. Occasionally, blockade of the lower cord (ulnar nerve or medial branch of the median nerve) can be incomplete. The morbidity of this technique is virtually nil.[226]

SUPRACLAVICULAR BRACHIAL PLEXUS BLOCK

In contrast to other brachial plexus blocks, risk for pneumothorax is increased because of the proximity of the lung parenchyma at this level. Use of ultrasound guidance with an in-plane approach is strongly recommended and allows real-time viewing of the needle tip, thus avoiding inadvertent pleural puncture.

Ultrasound-guided supraclavicular block in adults has been described in several articles, but few reports are available in the pediatric literature.[75,227,228] The brachial plexus trunks gather at the lower part of the interscalene space, where they surround the subclavian artery. This level carries the advantage of being the area where the trunks are most compact. With a high-frequency probe placed parallel and against the clavicle in the coronal oblique plane (Fig. 76.16), the brachial plexus (trunk or division) appears as a cluster of hypoechoic nodules located lateral, posterior, and superior to the subclavian artery (hypoechoic and pulsatile) and just above the underlying first rib (hyperechoic and curvilinear) (Fig. 76.17). Care should be taken to avoid intravascular injection of surrounding vessels (i.e., the suprascapular artery or dorsal scapular artery) by using color Doppler (Fig. 76.18). The needle is slowly advanced under direct visualization with an in-plane approach (from lateral to medial) toward the angle formed by the first rib and the subclavian artery (see Fig. 76.17). The goal of the supraclavicular technique is to see the spread of local anesthetic reaching the angle between the first rib and the subclavian artery. At Lurie Children’s, we primarily use this technique for brachial plexus blocks. In addition, we prefer testing the child regarding the integrity of the brachial plexus using a simple algorithm: a thumbs up sign (radial nerve); making an “O” with the thumb and index finger (median nerve); and scissoring the index and the third digit (ulnar nerve). Using this paradigm, we have been able to successfully delineate children who may not be eligible for nerve blocks due to preexisting nerve damage.[228]

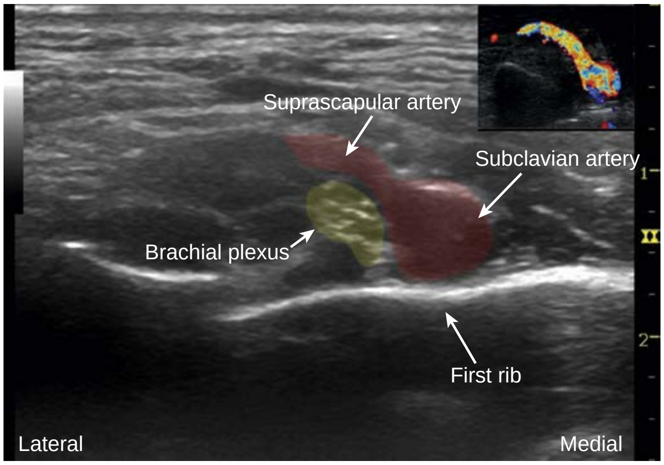

Fig. 76.18 Ultrasound supraclavicular block imaging and surrounding vessels by using color Doppler.

Ultrasound guidance has increased the safety profile of the supraclavicular approach so that in experienced hands this may be one of the most reliable and effective blocks of the brachial plexus.[224]

INFRACLAVICULAR BRACHIAL PLEXUS BLOCKS

Infraclavicular Approaches

Infraclavicular blocks have gained considerable interest, especially with the development of ultrasound guidance. They consist of approaching the divisions (close to the clavicle) or the cords (close to or below the coracoid process) of the brachial plexus. The two main approaches are midclavicular and paracoracoid, both performed with the patient in the dorsal recumbent position.[229] A catheter can be easily inserted and safely secured, which is not the case in the axilla area.

Midclavicular Approaches

Two midclavicular approaches, vertical and anterolateral, have been described. The vertical midclavicular approach is performed by inserting the needle at a right angle to the skin, immediately below the midpoint of the lower border of the clavicle, until twitches are elicited in the upper extremity. Even though use of this technique was reported in pediatric patients without apparent complication,[227,230] the path followed by the needle threatens the apical pleura and lung, thus contraindicating this approach in children.

The anterolateral midclavicular approach can be safely used in children lying supine with the ipsilateral arm alongside the thorax. The landmarks are the coracoid process of the scapula, the lower border of the clavicle, and the deltopectoral groove (Fig. 76.19). The block needle is introduced 1 cm below the midpoint of the lower border of the clavicle at a 30- to 45-degree angle dorsally and a 30-degree angle laterally, aligned with the deltopectoral groove, in direction to the axilla. The objective is to enter the neurovascular sheath 1.0 to 1.5 cm medial to the coracoid process of the scapula until twitches are elicited in the arm, forearm, or hand.

Paracoracoid Approaches

The medial paracoracoid approaches are currently the most popular techniques of infraclavicular blockade in children. It is the reference technique with nerve stimulation and the one with the lowest morbidity. The puncture site is located at the caudal extremity of the deltopectoral groove, 1 to 2 cm (according to patient's age) both caudally and medially to the coracoid (see Fig. 76.19). Abducting the upper arm at 90 degrees instead of placing it alongside the thorax brings the plexus closer to the skin and favors circumferential spread of local anesthetic.[231] The needle is inserted perpendicularly to the skin until twitches are elicited in muscles of the upper extremity.

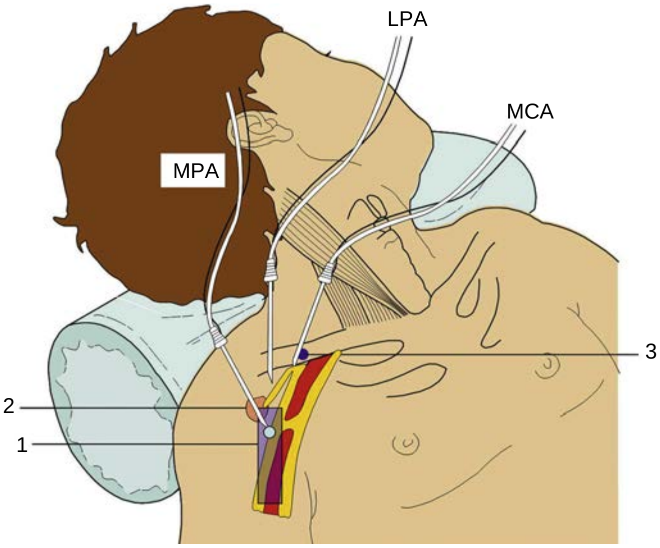

Fig. 76.19 Infraclavicular approaches to the brachial plexus. *LPA,* Lateral paracoracoid approach; *MCA,* midclavicular approach; *MPA,* median paracoracoid approach; *1,* ultrasound probe; *2,* coracoid process of the scapula; *3,* midpoint of the clavicle.

Ultrasound-Guided Infraclavicular Block

SUPRACLAVICULAR BLOCK

- Place a linear probe superior to the clavicle scanning lateral to the great vessels.
- Notice the first rib and the subclavian artery.
- The supraclavicular plexus is seen surrounding the subclavian artery as a “bunch of grapes.”
- Using an in-plane approach, place the needle below the plexus; injection of 0.2 mL/kg of local anesthesia will produce adequate analgesia.
- Stay away from using a medially positioned needle due to the close proximity to the pleura.

The lateral paracoracoid approach under nerve stimulation is technically feasible but unsafe if concomitant ultrasound imaging is not available, because of the danger of pleural penetration. The technique can be performed with the arm extended alongside the thorax or abducted 110 degrees and the elbow flexed by 90 degrees,[229] thus taking away the neurovascular sheath from the parietal pleura and loosening it to favor circumferential spread of the local anesthetic. Useful ultrasound landmarks are the axillary artery and vein, which are located deep and medial to the cords, with the vein positioned medial and caudal to the artery. Pectoralis major and minor muscles are most superficial overlying the neurovascular structures.

Two main infraclavicular approaches are used. One is a proximal approach with the probe placed parallel and

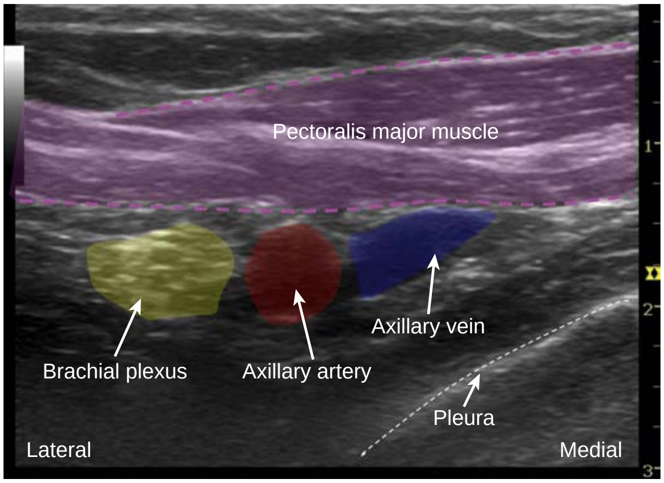

Fig. 76.20 Ultrasound infraclavicular block, infraproximal approach. At this proximal level, the pectoralis major is the main muscle seen superficial to the neurovascular bundle. The pectoralis minor is located distally to this ultrasound section. Among the neurovascular bundle structures the axillary vein is the most medial, followed by the axillary artery and then the divisions of the plexus most laterally.

immediately below the clavicle, and the cords are located lateral to the axillary artery (Fig. 76.20). The second is a paracoracoid approach with the probe placed in a parasagittal plane immediately medial and inferior to the coracoid process, allowing a short-axis view of the brachial plexus (Fig. 76.21). Many individual anatomic variations occur in the location of the cords around the artery. Commonly, the lateral cord is most easily viewed, the medial cord lies between the artery and vein, and the posterior cord is deep to the artery and frequently difficult to individualize. The needle is introduced using an in-plane approach from lateral (superior) to medial (inferior), and advanced aiming to place local anesthetic posterior to the axillary artery near to the posterior cord (Fig. 76.22).

Axillary Approach

AXILLARY BLOCK

- Place a hockey stick probe or a linear small footprint probe in the axilla as proximal as possible.
- The needle is directed from superior to inferior using an in-plane approach.
- The structures are located fairly superficially and can be easily identified.
- Color Doppler can be used to recognize the vascular structures.
- Local anesthetic solution is injected to surround the cords.

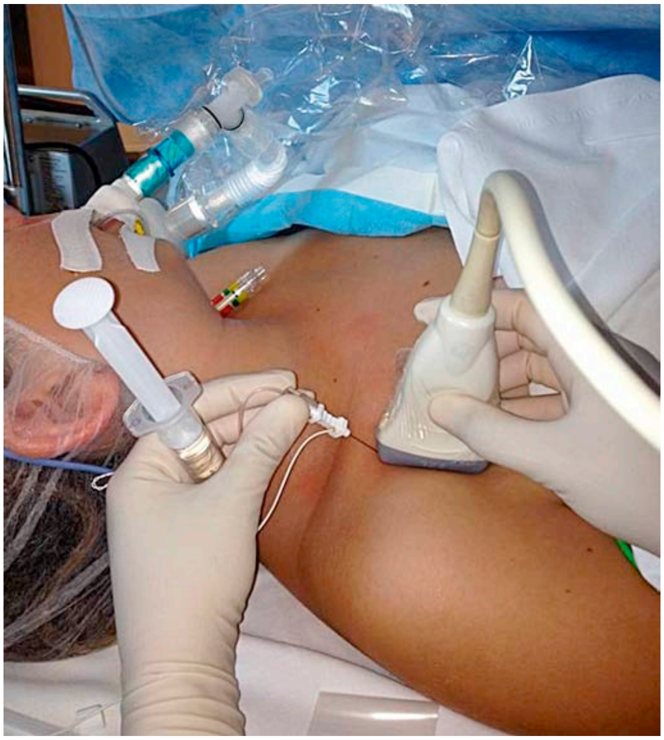

Fig. 76.21 Paracoracoid infraclavicular approach procedure, with probe position and in-plane needle insertion.

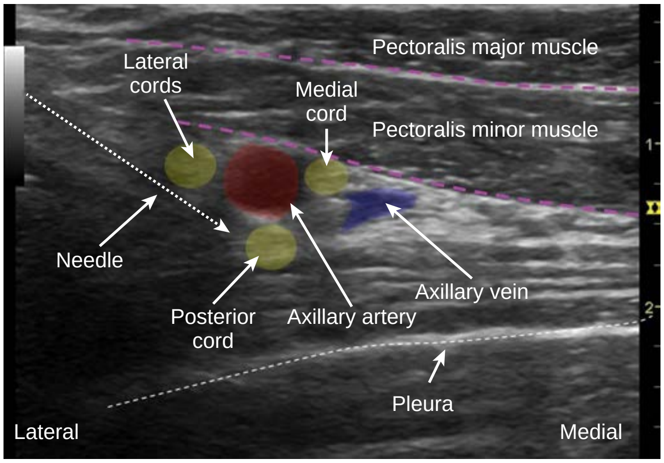

Fig. 76.22 Ultrasound infraclavicular block imaging by paracoracoid approach.

Historically, the axillary block was the most common approach to the brachial plexus in pediatric patients, aiming to approach the plexus at the level of its terminal branches in the axilla. It is a relatively easy and safe procedure to control perioperative pain in elbow, forearm, and hand surgeries. In children, several variants of the axillary approach have been described, with no difference in clinical outcomes regardless of the technique selected. In contrast to the procedure in adults, the transarterial approach is not used in children because of the higher incidence of vessel spasm and potential risk for ischemia. Unlike in adults, a single injection is sufficient to block all the nerves of the forearm and hand, with the exception of the musculocutaneous nerve in 50% of cases.[232] To overcome this problem, the most useful variant of this technique is the transcoracobrachialis approach. The child is placed in the supine position with the ipsilateral arm both supinated and abducted by 90 degrees.[220] The block needle is introduced posteriorly at the crossing of the coracobrachialis muscle with the lower border of the pectoralis major muscle (Fig. 76.23). The needle is advanced posteriorly toward the medial border of the humerus through the upper and lateral part of the coracobrachialis muscle (within which runs the musculocutaneous muscle). With nerve stimulation, the musculocutaneous nerve is usually the first nerve encountered

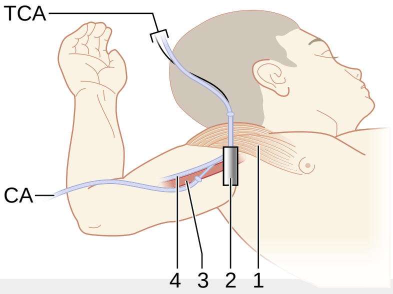

Fig. 76.23 Axillary approaches to the brachial plexus. *CA,* Classic approach; *TCA,* transcoracobrachialis approach; *1,* pectoralis major muscle; *2,* ultrasound probe; *3,* axillary artery; *4,* coracobrachialis muscle.

(it will be preferably blocked on removal of the needle); the needle is moved deeper until it crosses the perineurovascular sheath[218] and elicits twitches in the muscles of the hand and forearm. At this level the cords have split into terminal nerves, and the median nerve is usually contacted first. The local anesthetic is then injected, and the needle is removed while a small volume (0.1 mL/kg up to 5 mL) is injected close to the musculocutaneous nerve. All tourniquet pain (intercostobrachial nerve) can be blocked with a subcutaneous injection in the axilla.

With ultrasound guidance, a high-frequency probe is placed perpendicular to the major axis of the arm to obtain a short-axis view of the neurovascular bundle. The ultrasound-guided axillary approach to the brachial plexus is strictly a multi-injection technique. At this level, median, radial, and ulnar nerves are situated close to the axillary artery and vein. Great variation exists on the anatomic relationship of nerves with axillary location.[233] Generally, the median nerve is located between the lateral aspect of the artery and the biceps brachii muscle, the ulnar nerve is located more superficial and medial to the artery, and the radial nerve lies deep to the artery. Sliding the probe from distal arm to axilla area should help identify the nerve. The needle can be visualized throughout the procedure as it progresses in the plane of the ultrasound beam (Fig. 76.24); its tip can be precisely placed close to each of the three main nerves and, on removal of the needle, close to the musculocutaneous nerve between the coracobrachial and short head of the biceps muscles.

Axillary blocks are relatively safe. Accidental arterial puncture is the most undesirable complication, which may occasionally result in transient vascular insufficiency or a compressive hematoma. Intraneural injection is the most feared complication. It is usually thought to be the main cause of permanent nerve damage and mostly undetected in the patient under general anesthesia. In a prospective study on volunteers, Bigeleisen and associates[134] deliberately attempted to penetrate axillary nerve trunks under ultrasound guidance. Deliberate intraneural injections were made, and the patients were evaluated after the injection and 6 months later. No motor or sensory deficits were observed. Regardless of whether the design of this study is debatable, the results are interesting in showing that intraneural injection might not be as detrimental as commonly believed and might even be innocuous provided no intrafascicular injection (which elicits strong resistance to injection and excruciating pain) is made. However, such intraneural injections should be avoided, especially when ultrasound imaging is suggestive (tip of the needle within the nerve path and increase in nerve diameter when a fraction of the local anesthetic is being injected).

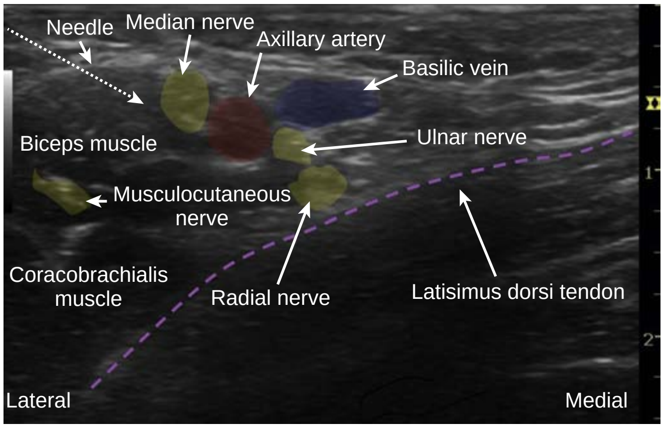

Fig. 76.24 Ultrasound-guided axillary block imaging.

TABLE 76.10 Usual Local Anesthetic Bolus Doses of Ropivacaine 0.1% (Neonate) to 0.2% or Levobupivacaine 0.125% (Neonate) to 0.25% and Infusion Rates for Brachial Plexus Nerve Blocks

Conduction Block	Bolus Doses (mL/kg)	Infusion Rates
Brachial plexus above and below clavicle	0.3-0.5	0.1-0.2 mL/kg/h
Any nerve trunk at elbow	0.1-0.2	—
Any nerve trunk at wrist	0.05-0.1	—

When continuous analgesia is required, a catheter may be introduced into the axillary nerve sheath, but its fixation and immobilization are difficult. Usually, periclavicular or interscalene approaches are preferred, with safe immobilization and increased patient comfort at these levels.

The volume of injectate is critical and depends on the approach and technique used to locate the nerves (Table 76.10). With nerve stimulation, no information is obtained regarding the circumferential spread around nerve trunks; thus recommended volumes of injection are based on the probability to obtain complete blockade. With ultrasound-guided techniques, the circumferential spread of local anesthetics can be clearly seen as a complete “donut” surrounding the relevant nerve trunk. In clinical practice, the use of ultrasound for nerve block must be associated with a significant reduction in the volume of local anesthetic.

DISTAL CONDUCTION BLOCKS

Elbow and Forearm Approaches

In pediatrics, approaching the radial, median, or ulnar nerve at the elbow or wrist is still not very common. These approaches are rather difficult with nerve stimulation only, and their failure rate is relatively high when blind subcutaneous injections are made. Indications have long been limited to complementation of partially failed brachial blocks.

Ultrasound imaging is widening the field of indications for these techniques because these superficial nerves are easy to identify and approach with ultrasound guidance, the more so as very small amounts of local anesthetic (0.05 mL/kg up to 1-2 mL) are sufficient to produce complete nerve blockade. It is possible to block median and ulnar nerves at any point of their route from the wrist to the axilla, but at the level of the wrist, caution is necessary because it is often difficult to distinguish the nerves from the tendons owing to their similar appearance.

- The median nerve is located in the antecubital fossa just medial to the brachial artery (Fig. 76.25). In the middle of the mid forearm, the median nerve is medial to the radial artery and medial and superficial to the radius (Fig. 76.26). At the wrist, the medial nerve is located between the tendons of the palmaris longus and the flexor carpi radialis but the distinction between the nerve and tendons may be difficult.
- The ulnar nerve can be blocked several centimeters above (Fig. 76.27) or below the elbow but never in the cubital tunnel, the groove between the olecranon and the medial epicondyle, because it can be compressed in this poorly compliant space. At the wrist, the ulnar nerve appears as a small hyperechoic triangle in close proximity to the medial side of the ulnar artery (Fig. 76.28*A*). To facilitate and secure the procedure, we prefer to track the ulnar nerve proximally until it separates away from the artery (see Fig. 76.28*B*).
- The radial nerve travels posterior to the humerus to the lateral side of the elbow, where it divides into superficial and deep branches. When scanning the posterolateral aspect of humerus just above the elbow, the radial nerve can be visualized below the brachial muscle in close proximity to the humerus (Fig. 76.29).

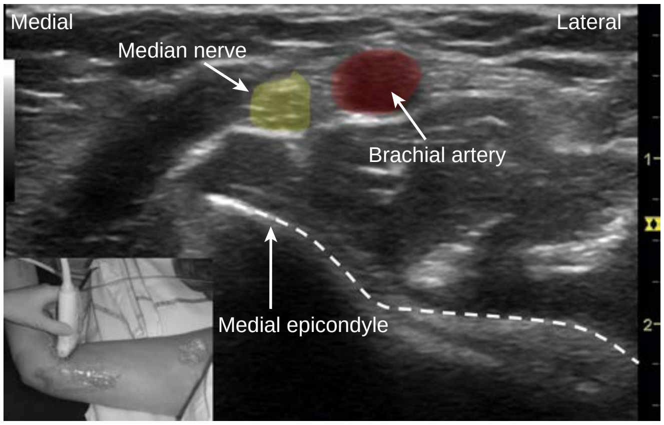

Fig. 76.25 Ultrasound view of median nerve at the elbow level.

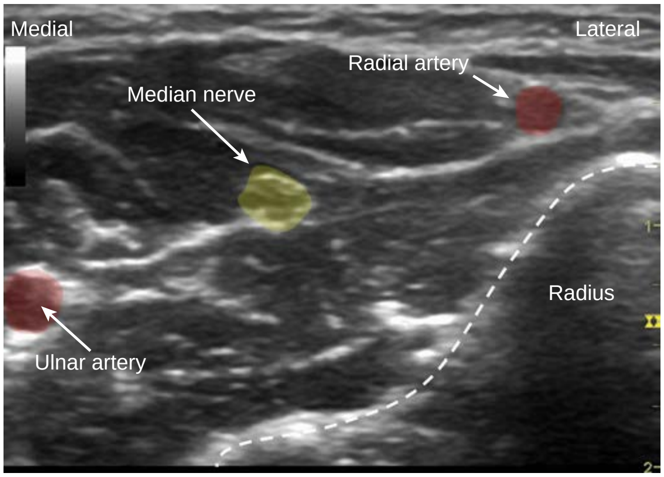

Fig. 76.26 Ultrasound view of median nerve at the midforearm.

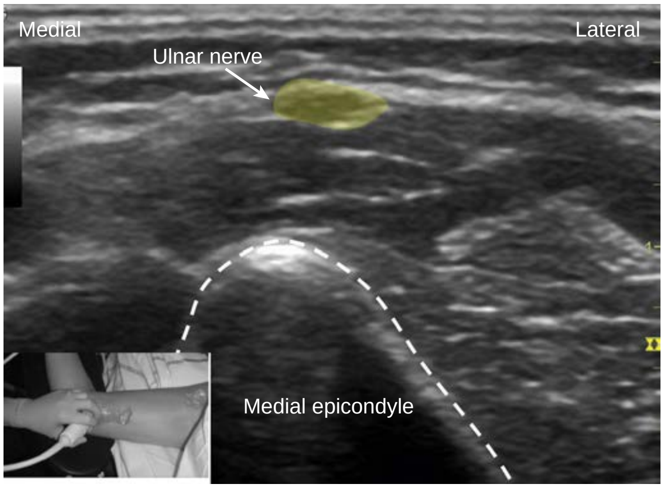

Fig. 76.27 Ultrasound view of ulnar nerve at the elbow.

DIGITAL BLOCKS

Traditional digital ring blocks are almost never used in children, at least by anesthesiologists, because of technically safer alternatives such as metacarpal block and subcutaneous infiltration.

A single, subcutaneous digital block was developed with the rationale of avoiding introduction of fluid into the digital flexor tendon sheath and a theoretic risk for infection. The subcutaneous block is performed by a single injection with a 25-gauge needle into the palmar skin at the base of the finger (Fig. 76.30).[234]

Note that these palmar techniques, including single subcutaneous palmar block, carry a risk for anesthetizing only the last two phalanges and the ventral aspect of the proximal phalanx of the fingers.

Lower Extremity Conduction Blocks

LUMBAR PLEXUS NERVE BLOCKS

Anatomic Considerations

The lumbar plexus is formed by the union of the anterior rami of the first four lumbar nerves (L1-L4) with variable input from the 12th thoracic nerve (T12) and L5. The lumbar plexus lies in the psoas compartment in the paravertebral space, with the anterior border formed by the psoas major muscle and the posterior border formed by the quadratus lumborum muscle. As it emerges from this space, it divides into the four nerves that innervate the anterior portion of the upper aspect of the lower extremity—the femoral, lateral cutaneous, genitofemoral, and obturator nerves. These nerves run a variable part of their course just

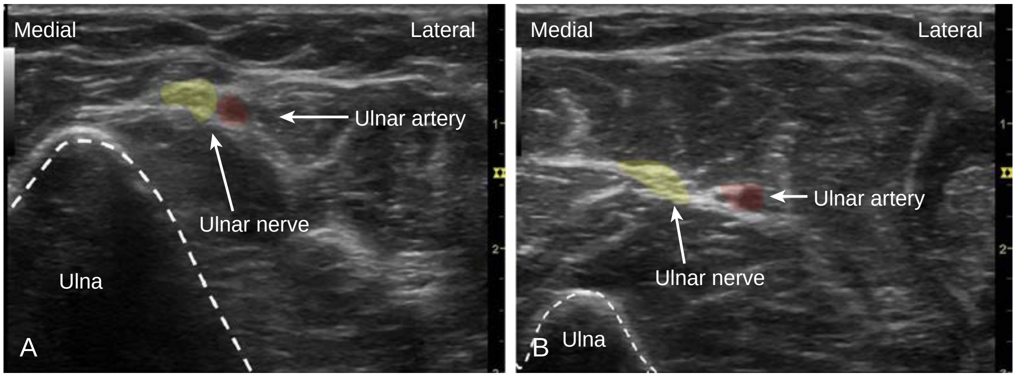

Fig. 76.28 Ultrasound view of ulnar nerve at the wrist (A) and at midforearm level (B).

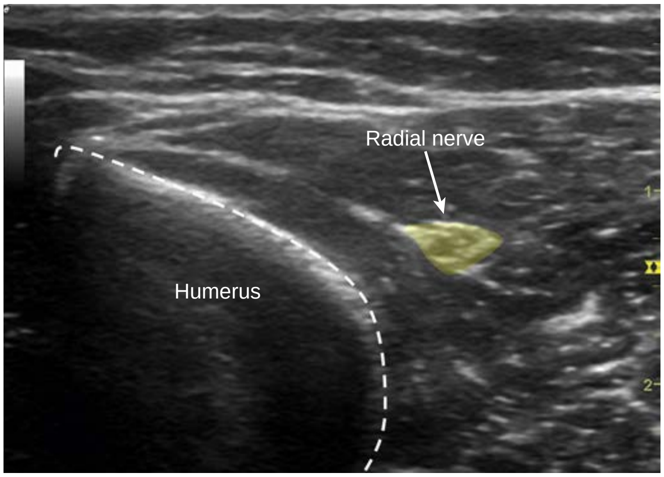

Fig. 76.29 Ultrasound view of radial nerve at the posterolateral aspect of the midarm.

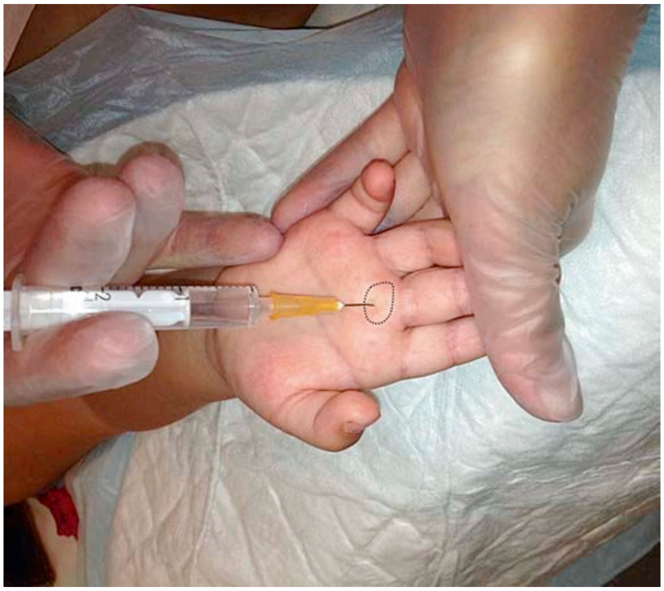

Fig. 76.30 Transthecal nerve block. The head of the metacarpal bone is located by palpation.

below the fascia iliaca, which is the common fascia covering psoas and iliacus muscle. A sufficient volume of local anesthetic injected at the inner surface of this fascia will spread along it and reach these nerves, thus producing a fascia iliaca compartment block.

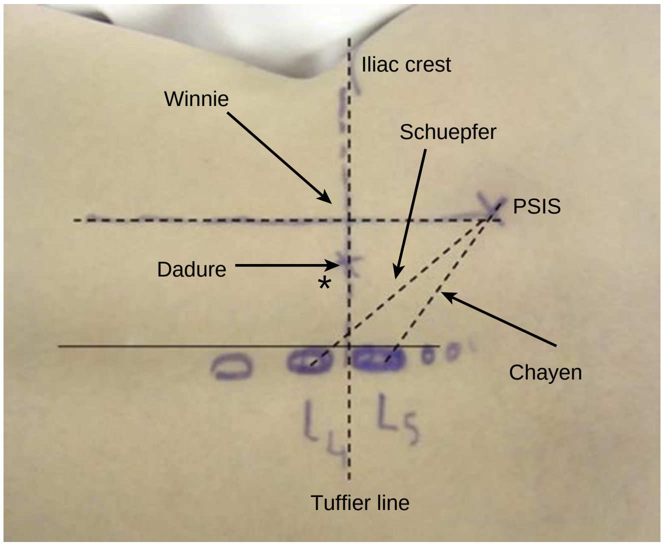

Fig. 76.31 Landmarks of psoas compartment block with different procedures described in the pediatric literature. *PSIS,* Posterior superior iliac spine.

Psoas Compartment Block (Direct Lumbar Plexus Block)

Psoas compartment block is performed with the child turned in the lateral decubitus position with the operated side uppermost. The landmarks are the iliac crests, the ipsilateral posterior superior iliac spine, and the L5 spinous process. The following three puncture sites can be used (Fig. 76.31):

1. The midpoint of the line joining the posterior iliac spine to the L5 spinous process (modified Chayen approach)
2. A point located on the intercristal line (Tuffier line), three quarters of the distance between the spinous process of L4 and a line parallel to the spinal column passing through the posterior superior iliac spine[235]
3. A point located at medial two thirds and the lateral one third on a line from spinous process of L4 to the posterior superior iliac spine[236]

Whatever the puncture site used, the block needle is inserted perpendicularly to the skin until twitches are elicited in the ipsilateral quadriceps muscle. Complications, including cardiac arrest from intravascular injection, psoas muscle hematomas, epidural anesthesia, and retroperitoneal injection if the needle is inserted deeper than recommended, have been reported.[237,238] Consequently, this

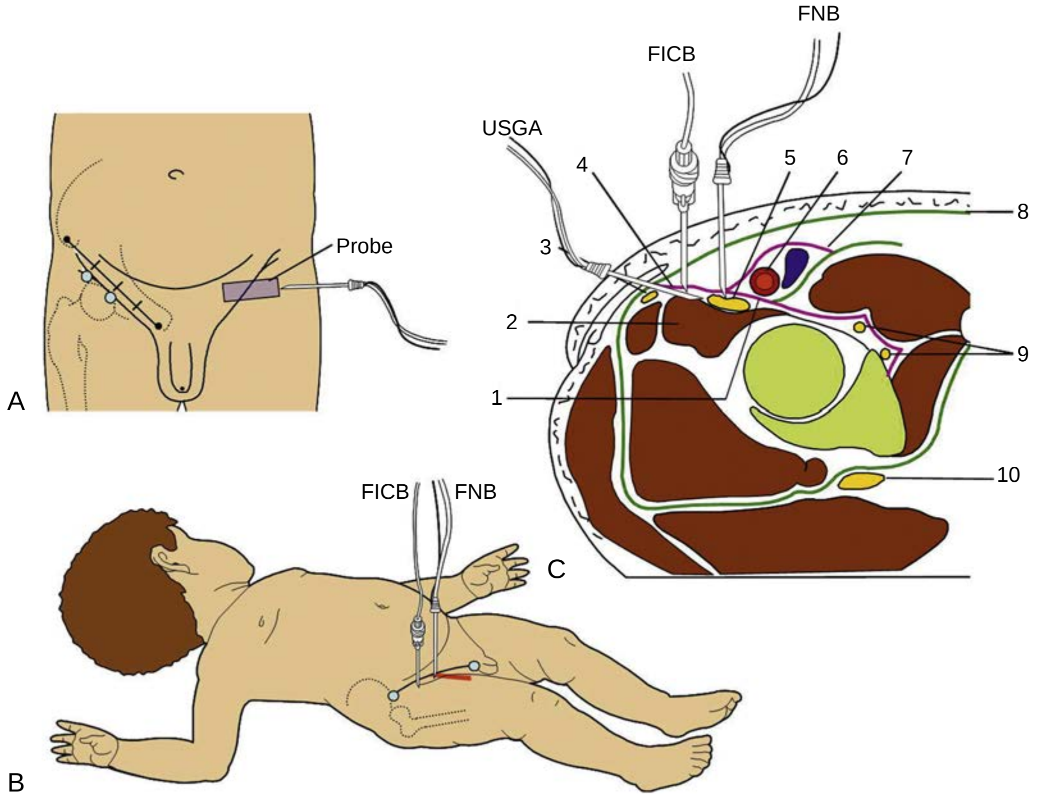

Fig. 76.32 Femoral nerve and fascia iliaca compartment blocks. (A) Landmarks and probe positioning. (B) Patient position. (C) Transverse section of the thigh. *FICB,* Fascia iliaca compartment block; *FNB,* femoral nerve block; *USGA,* ultrasound-guided approach; *1,* iliopectineal arch; *2,* psoas muscle; *3,* lateral cutaneous nerve of the thigh; *4,* fascia iliaca; *5,* femoral nerve; *6,* femoral artery; *7,* femoral vessel sheath; *8,* fascia lata; *9,* division branches of the obturator nerve; *10,* sciatic nerve.

regional technique should be performed only by trained anesthesiologists, taking into consideration the depth of the lumbar plexus estimated according to the patient's age or weight and the proximity of important anatomic structures to the psoas compartment.

The usual indications for this block are surgeries on the hip or femoral shaft (femoral and hip osteotomies). These operations require blockade of the three main nerves innervating the hip joint: femoral, lateral femoral cutaneous, and obturator nerves. Psoas compartment block can produce excellent postoperative pain management during the first 48 hours. A recent study using sonography of the lumbar plexus in children showed that the depth of the lumbosacral plexus correlated with weight rather than age.[239] Continuous psoas compartment block provides good management of pain relief in major hip or femoral surgeries in children.[125,235,240] Continuous psoas compartment block has been compared with continuous epidural block in hip and femoral surgery in children.[125] Continuous psoas compartment block provided the same quality of postoperative analgesia with significantly less adverse events and required decreased doses of ropivacaine than continuous epidural block.

Femoral Nerve Block

Femoral nerve blocks are performed while the child lies supine, preferably with the ipsilateral limb slightly abducted. The landmarks are the inguinal ligament and the femoral artery. The puncture site is located 0.5 to 1.0 cm both below the inguinal ligament (not the inguinal crease) and lateral to the femoral artery (Fig. 76.32). The block needle is inserted posteriorly, either perpendicular to the anterior aspect of the thigh or, especially when a catheter has to be inserted, at a 45-degree angle cephalad, pointing to the umbilicus, until twitches are elicited in the quadriceps muscle when nerve stimulation is used.

Ultrasound imaging makes the technique even easier.[141] The probe is placed slightly above and parallel to the inguinal ligament (Figs. 76.33 and 76.34).

The main surgical indications are femoral shaft or knee surgeries. The introduction of a catheter for continuous analgesia can be achieved by the direct perineural (femoral) approach[241] or the fascia iliaca compartment approach.[242,243] These two approaches have never been compared in terms of efficacy in children.[244] The fascia iliaca technique, which does not require the use of a nerve stimulator or mobilization of the limb, seems easier to perform in fractures of the femur with less accidental vascular puncture.

Fascia Iliaca Compartment Blocks

The technique consists of injecting a local anesthetic below the fascia iliaca.[244] The injectate spreads at the inner surface of the fascia and, depending on its volume, spreads around the nerves emerging from the lumbar plexus that supply the lower extremity. The technique is performed with the child lying supine (see Fig. 76.32). With this technique, the femoral and lateral cutaneous nerves are almost constantly blocked. The local anesthetic usually reaches the upper division branch of the obturator nerve, which is the branch giving a twig to the hip joint. The anesthetized area also includes areas supplied by upper branches of the lumbar plexus in more than 70% of procedures, such as the genitofemoral nerve.

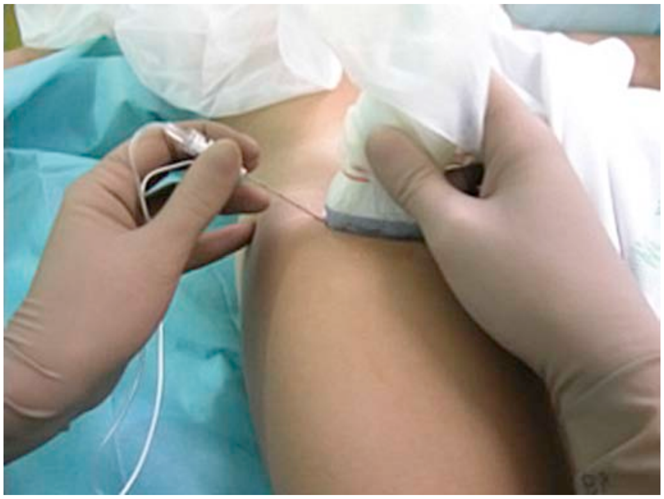

Fig. 76.33 Probe location for ultrasound in-plane femoral block procedure.

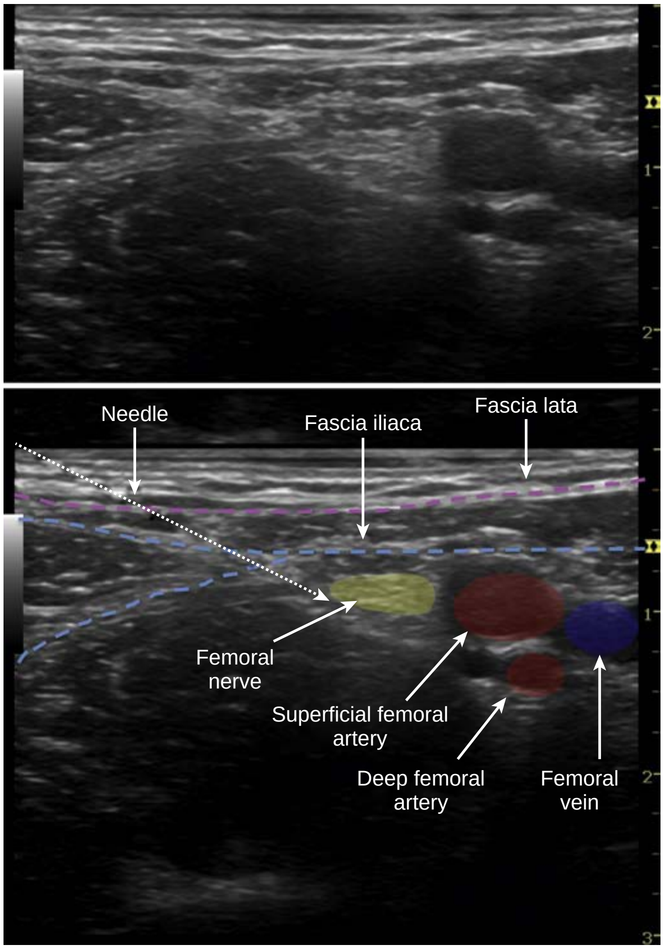

Fig. 76.34 Ultrasound picture of femoral nerve block procedure.

Perivascular femoral nerve and fascia iliaca compartment approaches have never been compared in terms of efficacy in children.[244] The fascia iliaca compartment block was superior in terms of blockade for lateral femoral cutaneous, obturator, and genitofemoral nerves. The perivascular approach provides a risk for significant vascular puncture. Moreover, the fascia iliaca technique, which does not require the use of a nerve stimulator or mobilization of the limb, seems easier to perform in femur fracture surgeries.

Performing this block using ultrasound showed several advantages, including extension of the duration of postoperative analgesia and decrease in the volume of injected local anesthetic in contrast to that with nerve stimulation technique. Recent reviews comparing use of ultrasound to no ultrasound demonstrated increased block duration and better pain scores in the postanesthesia unit, as well as higher block success rates.[1,141] Oberndorfer and associates found that the duration of analgesia in the ultrasound group was significantly increased to approximately 508/178 minutes versus approximately 335/69 minutes for sciatic and femoral nerve blocks using the same techniques.[141]

Usual doses of local anesthetic are 0.2 to 0.5 mL/kg in single-shot or induction bolus and 0.1 to 0.2 mL/kg/h in postoperative continuous infusion of long-acting local anesthetic.[126] Patient-controlled regional anesthesia can be used with bolus of 0.1 mL/kg (up to 5 mL, and maximum 3 boluses per hour). Local anesthetics with epinephrine produce significantly lower plasma concentrations and should be preferred whenever possible. The addition of clonidine (1-2 µg/kg)[60] significantly prolongs the duration of analgesia.[44]

In fascia iliaca compartment and femoral nerve block, placement of a catheter is easy and allows long-lasting pain relief (Fig. 76.35) and is improved with ultrasound guidance. Recently, Lako and associates[243] compared continuous fascia iliaca block and intravenous morphine in terms of analgesia and side effects in children undergoing pelvic osteotomy. The authors noted excellent postoperative pain relief, with less sedation and a better return of appetite in the regional analgesia group in contrast to the morphine group. On the other hand, Paut and colleagues[242] determined plasma concentrations of bupivacaine during continuous fascia iliaca block in children after major femur or knee surgery or femoral fracture. The regimen of local anesthetic administration was a bolus dose of 0.25% bupivacaine with epinephrine followed by continuous administration of 0.1% bupivacaine for 48 hours. They concluded that the plasma concentrations of bupivacaine during continuous fascia iliaca compartment block are within the safety margins for children (0.71 ± 0.4 g/mL and 0.84 ± 0.4 g/mL at 24 hours and 48 hours, respectively).

Other Lumbar Plexus Nerve Blocks

SAPHENOUS NERVE BLOCK GUIDANCE

- Place a linear probe along the medial aspect of the lower third of the thigh
- The artorius and the superficial femoral artery are identified, a needle is inserted in an in-lane approach
- The local anesthetic is injected to surround the nerve that is located in the fascial plane between the sartorius and the vastus medialis muscle but superficial to the superficial femoral artery
- Frequent aspiration of the needle is performed to reduce intravascular injections

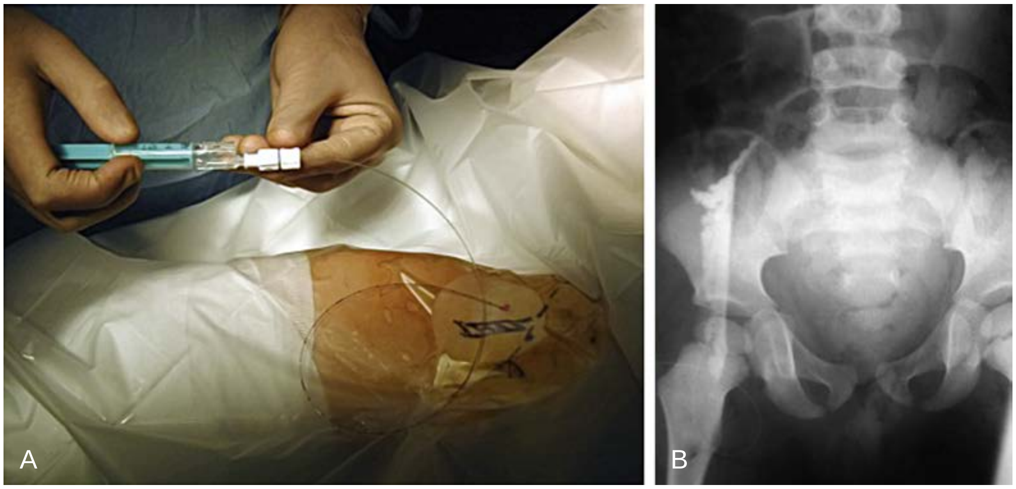

Fig. 76.35 Femoral nerve catheter placement (A) and spread of contrast medium solution after injection into the catheter (B).

Saphenous Nerve Block. Saphenous nerve blocks are used as a complement to sciatic blocks with small amounts of local anesthetic. Because the saphenous nerve is a purely sensory nerve, it is not identifiable by nerve stimulation. This block is also alluded to as the adductor canal block and has gained immense popularity especially for lower extremity procedures in which motor block can be avoided. Many block procedures have been published, all resulting in a high failure rate (30% or higher). Ultrasound guidance has greatly facilitated this block placement.

The classic approach is performed at knee level with the patient supine. The anterior edge of the medial head of the gastrocnemius muscle and the tibial tuberosity are identified by palpation. A line is drawn at a 45-degree angle with the intercondylar line, from the tibial tuberosity to the anterior edge of the gastrocnemius muscle. The technique consists of subcutaneously injecting local anesthetic along this line. This very simple technique is virtually free of complications, but its failure rate is rather high.

The saphenous and vastus medialis nerve block takes advantage of the proximity of the vastus medialis and saphenous nerves within the adductor canal in the upper part of the thigh. Being a mixed nerve, the vastus medialis nerve can be located easily by nerve stimulation, and injecting a local anesthetic, which results in concomitant blockade of the two nerves. The landmarks are the femoral artery, the inguinal ligament, and the upper border of the sartorius muscle (Fig. 76.36). A short and short-beveled insulated needle is inserted perpendicularly to the skin, 0.5 cm lateral to the femoral artery just above the upper border of the sartorius until twitches are elicited in the vastus medialis muscle. Injecting 0.1 to 0.2 mL/kg of a local anesthetic is sufficient to block the two nerves and obtain complete analgesia of the medial aspect of the leg and foot.

Ultrasound guidance is now commonly used for saphenous and vastus medialis nerve block. Using a linear high frequency probe and with the limb slightly laterally rotated, the sartorius muscle is scanned and the subsartorial area is identified. The vastus medialis muscle is then identified and the facial plane separating the vastus medialis from the sartorius is identified. The saphenous nerve is located in close proximation to the superficial femoral artery. Local anesthetic is injected under direct ultrasound guidance around the nerve plexus.

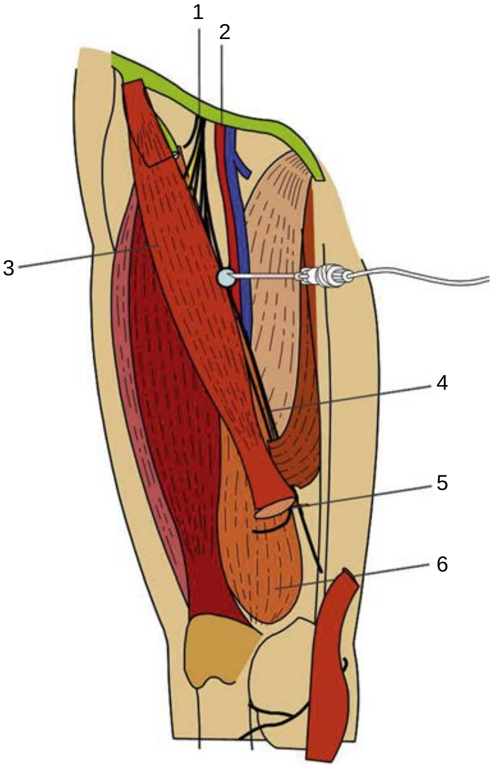

Fig. 76.36 Saphenous and vastus medialis nerve block. *1,* Femoral nerve; *2,* femoral artery; *3,* sartorius muscle; *4,* saphenous nerve; *5,* motor nerve supplying the sartorius muscle; *6,* vastus medialis muscle.

Lateral Femoral Cutaneous Nerve Block. A specific lateral cutaneous nerve block is rarely used solely for analgesia in children; its main indication is as a technique complementary to a femoral block. The block can be used for providing analgesia for fascia lata grafts, femoral pinning, and for muscle biopsies. Ultrasound guidance has made the performance of this block easy and safe.

Performance of the block: A linear probe is placed below the anterior superior iliac spine (ASIS); the sartorius is identified. The potential space between the tensor fascia lata and the sartorius houses the lateral femoral cutaneous nerve between the fascia lata. It is a potential space and has hardly any complications. The old technique using ‘pops’ for LOR has now been abandoned for the aforementioned ultrasound-guided technique.

LATERAL FEMORAL CUTANEOUS NERVE BLOCK: ULTRASOUND GUIDANCE.

- Palpate the groove between the sartorius and the tensor fascia lata just below the anterior superior iliac spine.
- A linear high-frequency probe is placed below the anterior superior iliac spine; the sartorius can be imaged as a triangular structure close to its insertion with the tensor fascia lata lateral to that.
- The fascia iliaca compartment is seen in the groove between the tensor fascia lata and the sartorius and the lateral femoral cutaneous nerve is located in this space.
- After aspiration, the compartment is filled with local anesthetic solution. Large volumes can spread to the femoral nerve and can result in a motor block.

Obturator Nerve Block. This procedure is performed with the child supine and the thigh slightly abducted and externally rotated (if possible). The landmarks are the groove between the tendon of the long adductor muscle and medial border of the pectineus muscle. The puncture site lies in this groove at the level of the greater trochanter of the femur. With nerve stimulation, the needle is inserted following a strict anterior-to-posterior path until twitches are elicited in the long and short adductor muscles (stimulation of the anterior division branch of the obturator nerve). The needle is further advanced dorsally over 1 to 2 cm until twitches are elicited in the great adductor (posterior branch). Half of the local anesthetic solution (of a total of 0.1 mL/kg up to a maximum of 5 mL per nerve) is injected; the needle is then removed until stimulation of the anterior branch is obtained again and the second half of the anesthetic is injected.

The technique can be performed with ultrasound guidance. The probe is placed below the pubic tubercle, with its major axis parallel to the inguinal ligament. The aponeuroses of the sartorius and long and short adductors are easily identified. The anterior branch can be easily found between the long and short adductors, and the posterior branch lies between the short and great adductors (Fig. 76.37).

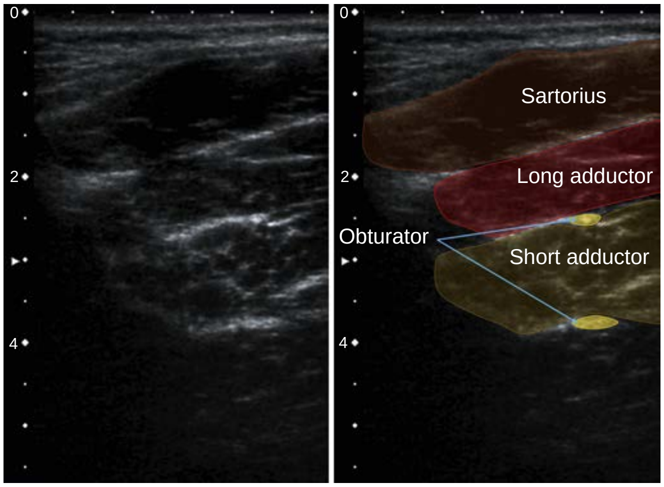

Fig. 76.37 Obturator nerve block, with ultrasound imaging of the anterior and medial aspect of the thigh.

SCIATIC NERVE BLOCKS

Anatomic Considerations

The sacral plexus is formed by the anterior rami of the fourth and fifth lumbar nerves and the first three sacral nerves with variable input from the fourth sacral nerve. The sacral plexus lies on the surface of the sacrum anterior to the piriformis muscle. The sacral plexus gives rise to the other two nerves that innervate the lower extremity: the posterior cutaneous nerve of the thigh (otherwise known as the small sciatic nerve) and the sciatic nerve. Peripheral blockade of these two nerves is considered together as blockade of the sciatic nerve. These two nerves travel together in the same sheath as they exit through the greater sciatic foramen into the posterior aspect of the upper part of the leg. The sciatic nerve runs in the midline of the posterior aspect of the thigh to the apex of the popliteal fossa. At the level of this fossa, it divides, at a variable distance, into the common peroneal and the posterior tibial nerves. The common nerve continues its descent around the head and neck of the fibula. The terminal branches form the superficial and deep peroneal nerves. The tibial nerve runs in the internal face of the leg and emerges laterally and behind the tibial artery at the level of the lateral malleolus. Its terminal branches are the lateral and medial plantar nerves.

Indications and Contraindications

Sciatic nerve blocks are recommended for operations on the foot and the leg (an additional saphenous nerve block is often required because this nerve provides cutaneous innervation of the medial aspect of the leg). Depending on the surgery, the sciatic nerve will be approached in the popliteal fossa or more proximally. Sciatic blocks have no specific contraindications. As with other extremity nerve blocks, patients at risk for compartment syndrome require close monitoring and use of diluted solution to avoid motor blockade.

Proximal Sciatic Nerve Blocks

Numerous techniques have been described for which the associated morbidity can differ significantly. When successful, they provide the same distribution of anesthesia. When contemplating a proximal sciatic block, the anesthesiologist must consider (1) morbidity of the technique, (2) positioning of the patient, (3) technique used to locate the nerve, (4) necessity for catheter placement, and (5) experience of the anesthesiologist with this particular technique.

Subgluteal Approach. The subgluteal approach is a common proximal way to the sciatic nerve in children. This block can be performed in a supine, lateral, or prone position. In supine position, the leg is flexed to 90 degrees at the hip with the knee flexed at 90 degrees (Fig. 76.38). This position is preferable in small children. In older ones, the lateral or prone position is preferred. The point of puncture is located at the midline joining the ischial tuberosity and the greater trochanter of the femur. The needle is inserted at right angles to the skin toward the femur until twitches are elicited in the foot. The nerve is easily accessible, is relatively superficial, and lies in a palpable groove.

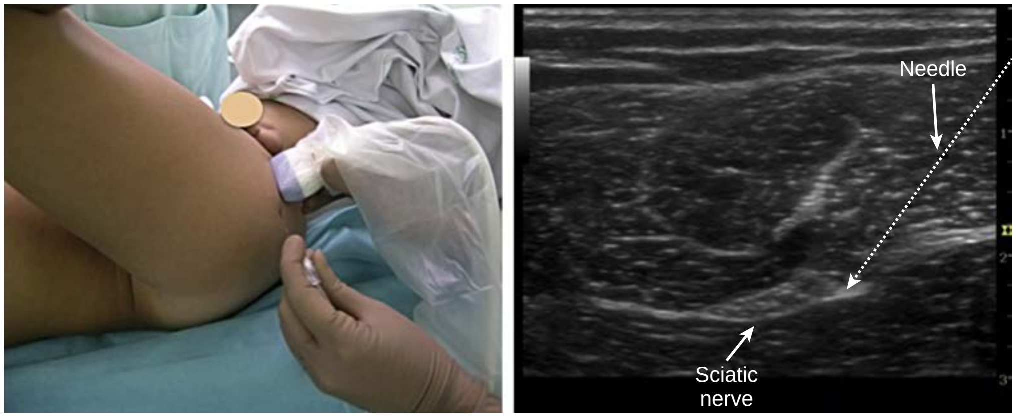

Fig. 76.38 **Position and ultrasound visualization of the in-plane subgluteal approach to sciatic nerve.**

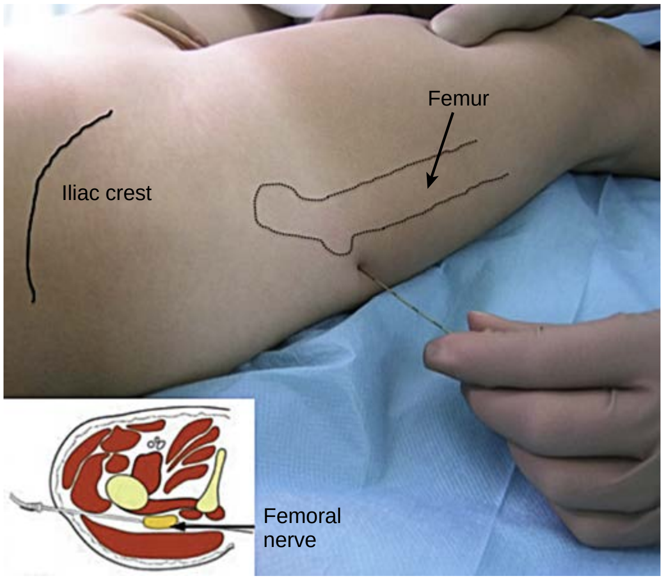

Fig. 76.39 **Proximal sciatic lateral block procedure.**

Ultrasound guidance with or without nerve stimulation facilitates the success of this block.[245] Continuous subgluteal block can be easily performed and permits good postoperative pain management in major ankle or foot pediatric surgery.[245]

Lateral Approach. A lateral approach to the sciatic nerve has been described for use in patients lying supine[246] with the relevant leg slightly rotated medially. The needle is inserted horizontally toward the lower border of the femur (Fig. 76.39). If bone contact is made, the needle is withdrawn and reinserted slightly more posteriorly until twitches are elicited in the leg and the foot. The distance at which the sciatic nerve is found can be correlated with patient age (Fig. 76.40).

Proximal lateral sciatic nerve blocks have been described for major foot surgery in children, but with high doses of local anesthetics and catheter migration or dislodgement maintained during patient mobilization.[247,248] It has been described in children with the same landmarks and technique of puncture described later. The catheter can be fixed with transparent dressing or tunneled to permit more stable fixation and prolonged administration.

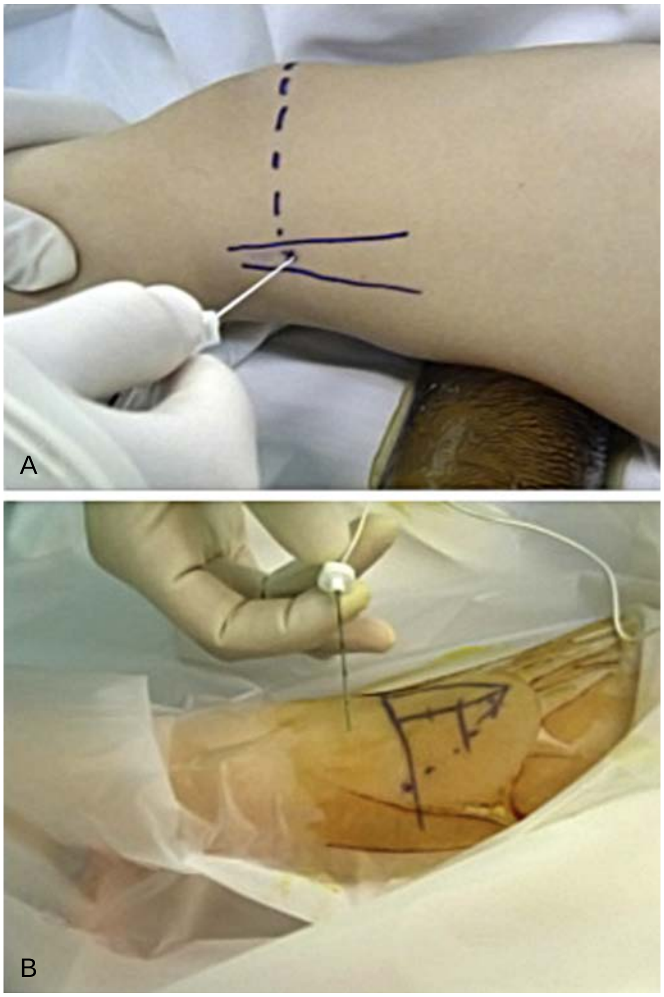

Fig. 76.40 Sciatic popliteal nerve block with lateral approach (A) and posterior modified Singelyn technique approach (B).

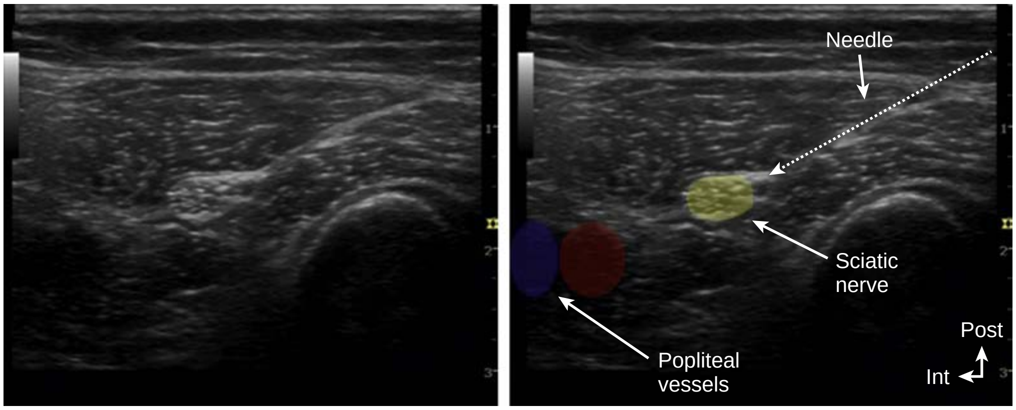

Fig. 76.41 Ultrasound of sciatic popliteal nerve block. Sciatic nerve is usually located laterally and superficially to the popliteal vessels.

Popliteal Sciatic Approach

SCIATIC NERVE BLOCK AT THE POPLITEAL FOSSA

- Place a linear probe in the popliteal fossa at the crease at the knee.
- Look for the popliteal artery.
- The popliteal vein is noted above the artery.
- The tibial nerve is often located in close proximity to the popliteal artery.
- The common peroneal nerve is located lateral to the tibial nerve.
- A linear probe is gently moved cephalad until the confluence of the two branches; the nerve will diverge from the vessels.
- Using an in-plane approach, a needle is placed in close proximity to the sciatic nerve and local anesthetic solution is injected to surround the nerve.

Popliteal nerve block is a simple, safe, and effective method, providing good analgesia with small amounts of local anesthetics. This approach is our first choice for major foot and ankle surgeries in children. The two approaches to the sciatic nerve in the popliteal fossa are the lateral and posterior approaches. The child may remain in the supine position for the lateral approach. The landmark for lateral distal sciatic nerve approach is the groove between the vastus lateralis muscle and the tendon of the long head of the biceps femoris muscle at the level of the superior edge of the patella (Fig. 76.41*A*). In the posterior approach, the child is placed in the prone or, preferably, the semiprone position, resting on the nonoperated side. A popliteal sciatic nerve block with posterior approach is performed using the landmarks of Singelyn and colleagues[249] adapted to children (see Fig. 76.41*B*). A nerve stimulator may be used to assist the practitioner to identify the nerve. Correct needle placement is identified when an output 0.6 mA elicits a characteristic motor response corresponding to either tibial (dorsiflexion of the foot) or common peroneal (foot eversion) nerve stimulation.

Ultrasound guidance has become the choice method for performing this block, allowing an in-plane or out-of-plane approach depending on the habits of the practitioner. Ultrasound scanning permits the location of the sciatic nerve and its division in popliteal fossa.[245,250] The sciatic nerve is usually located laterally and superficially to the popliteal artery (see Fig. 76.41). Ideally, the sciatic nerve should be blocked before its division into tibial and common peroneal nerves to obtain the best result. This can be corroborated with nerve stimulation to verify placement of the block.

Pain management for major foot and ankle surgery requires continuous sciatic nerve block. The distal approach is particularly interesting because of the ease of performance and the quality, power, and duration of analgesia with low doses of local anesthetics.[67,157,251,252] Continuous popliteal nerve block was compared with continuous epidural block in children undergoing major foot and ankle surgery.[252] Both techniques were associated with excellent postoperative analgesia in this study, but continuous popliteal nerve block led to less urinary retention, less discontinuation of local anesthetic infusion, and less nausea and vomiting. The popliteal catheter is the location most frequently used to treat children at home.[80,156]

Metatarsal Blocks

The metatarsal (or midtarsal) block is an easy technique for providing good pain relief for surgical procedures on the toes. The child is placed supine, and the head of the relevant metatarsal is palpated on the sole. The technique consists of inserting a standard intramuscular needle dorsally on the dorsum of the foot in close contact with the medial border of the base of the metatarsal until the tip of the needle is felt and seen as it pushes the skin of the sole. A volume of 1 to 3 mL of local anesthetic is then injected while the needle is slowly withdrawn. The same procedure is repeated along the lateral border of the same metatarsal to provide full anesthesia of the relevant toe.

Truncal Blocks

Surgeries of the trunk are some of the most common surgeries performed in children. Traditionally, central neuraxial blocks are frequently used for these procedures. Nevertheless, central neuraxial blocks have some adverse effects, including unwanted motor block, urinary retention, pruritus, nausea and vomiting, and risk for spinal cord injury or epidural hematoma. Globally, peripheral nerve blocks are increasingly utilized in the practice of pediatric anesthesia.[99] Abdominal wall blocks are known as effective techniques to provide adequate analgesia for minor abdominal surgery in children. The use of ultrasound guidance has increased the utilization of these blocks especially in children.

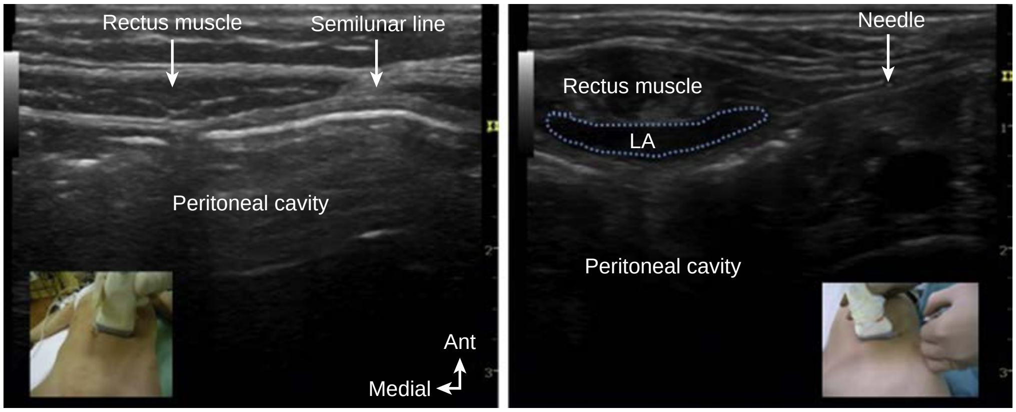

Fig. 76.42 Ultrasound of paraumbilical block. Insertion of the needle close to the posterior fascia of the rectus muscle and injection of the local anesthetic creating a biconvex black cloud.

PERIPHERAL BLOCKS FOR ABDOMINAL WALL SURGERY

Rectus Sheath and Paraumbilical Block

The rectus sheath and paraumbilical block technique consists of injecting a local anesthetic within the substance of the rectus abdominis muscle along the course of the terminal branch of the tenth intercostal nerve, which supplies sensory innervation to the periumbilical area. It provides efficient pain relief for umbilical or other midline surgical incisions, as well as umbilical and epigastric hernia repair, laparoscopic surgery, and pyloromyotomy. Today, this regional anesthetic technique has become increasingly popular.[253]

Technique: Ultrasound guidance is used to demonstrate the various layers of the abdomen. The rectus abdominis muscle is clearly seen with the posterior rectus sheath and the peritoneal layer. A high-frequency linear probe is used; two punctures on each side of the umbilicus are necessary. A short beveled needle inserted at 45-degree angle is necessary to perceive the passage of different planes. The local anesthetic is deposited below the posterior rectus sheath; the potential space is noted to open up with the injected local anesthetic solution. Long-acting local anesthetics are usually used with a low concentration (0.2%-0.5%). The total volume of anesthetic solution injected is 0.1 to 0.5 mL/kg of body weight in each side.

Performing this block under ultrasound guidance can avoid intraperitoneal punctures and erratic needle position.[254] In contrast to the fascial-click method, ultrasound guidance significantly increases correct needle position (88% vs. 44%) and decreases the rate of intraperitoneal or injections that are too superficial (11.5% vs. 34.5% and 0% vs. 20.9%, respectively, for ultrasound-guided techniques and fascial click).[255] Both aponeuroses of the rectus muscle and the parietal peritoneum are very echoic. The probe is placed horizontally over the umbilicus, and the block needle is inserted medially in long-axis orientation. The superficial fascia is bent and then crossed by the tip of the needle, which should be moved forward until it contacts the deep fascia (to favor the longitudinal spread of the anesthetic). The anesthetic is then injected and can be visualized in the form of an expanding biconvex black shadow (Fig. 76.42).

Rectus Sheath Block

- A linear high-frequency probe or a hockey stick probe is placed at the level of the umbilicus.
- The rectus abdominis muscle is identified along with the anterior and posterior rectus sheaths.
- Using an in-plane technique, a 27-gauge needle is advanced until it penetrates the space between the rectus abdominis and the posterior rectus sheath.
- 0.1 mL/kg of local anesthetic solution is injected into the potential space between the posterior rectus sheath and the rectus abdominis muscle.
- Hydrodissection can be used to find the exact plane since the space is small and may need exact localization.

Ilioinguinal and Iliohypogastric Nerve Blocks

The three nerves supplying the inguinal area are the ilioinguinal, iliohypogastric, and genitofemoral nerves. In 50% of patients, sensory innervation of the inguinal canal depends exclusively on the genital branch of the genitofemoral nerve (also termed the external spermatic nerve in males). Several publications focusing only on the ilioinguinal and iliohypogastric nerves have appeared in the literature, especially with the introduction of ultrasound imaging.[140,256,257]

The ilioinguinal nerve block is effective in providing analgesia for inguinal area surgery including but not limited to inguinal hernia and hydrocele surgery in children. An additional injection of the genitofemoral nerve or local infiltration of the testicular sack is needed to provide complete analgesia for orchidopexy repair. This technique, widely described in the literature, is a fascial-click technique. A single-injection technique can safely and reliably block the three relevant nerves at once because these nerves are located in the same fascial plane close to the subcutaneous inguinal ring formed by the aponeurosis of the external oblique muscle. The landmarks are the umbilicus, ipsilateral ASIS, and midpoint of the inguinal ligament. The ASIS-umbilicus line is divided into four equal parts; the puncture site is located at the union of the lateral fourth with the medial three fourths (Fig. 76.43). A short-bevel needle is essential to perceive the passage of the various planes. The two main risks are intravascular injection (very low) and the crossing of three muscle layers with penetration into the abdominal cavity or intraperitoneal organ. In addition, the extension of the territory femoral anesthesia is a complication reported after ilioinguinal-iliohypogastric block with an incidence of up to 10%.[258] The usual dose is 2.5 mg/kg of long-acting local anesthetic. Puncture may be bilateral if the surgery requires. The risk for bowel trauma is present with the use of the

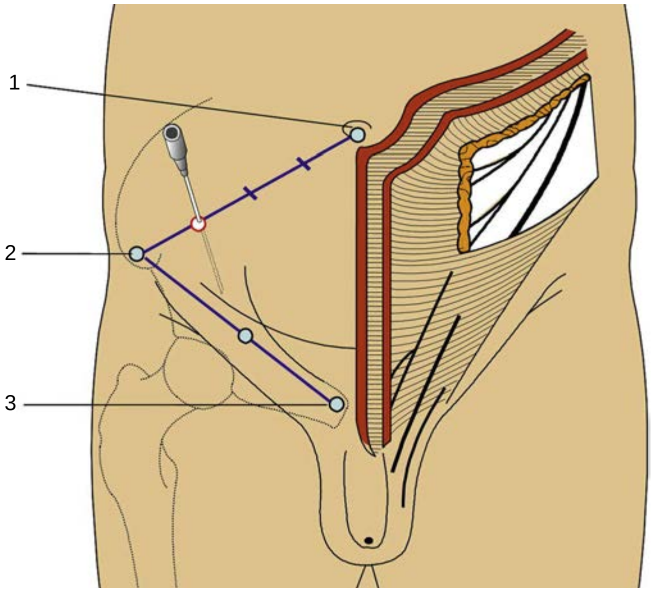

Fig. 76.43 Iliohypogastric and ilioinguinal nerve blocks. *1,* Umbilicus; *2,* anterior iliac crest; *3,* pubic spine.

facial click technique and our preferred methodology is to use ultrasound guidance for this block.

Ultrasound guidance of this block has advantages in terms of quality of analgesia and dose reduction of local anesthetics.[140] The probe is located on the line between the ASIS and umbilicus close to ASIS. We use a high frequency linear probe for this procedure. Two muscles of the abdominal wall are visible at this level: the transverse muscle and internal oblique muscle. The external oblique and internal oblique could at this level become a single aponeurotic layer. The neural target is located between both these muscles (Fig. 76.44). The needle insertion can be performed with an in-plane or out-of-plane technique. Willschke and associates[140] showed that the total volume of local anesthetic used in the ultrasound group was significantly lower than in the fascial-click technique (respectively, 0.19 mL/kg vs. 0.3 mL/kg of 0.25% levobupivacaine). They concluded that the local anesthetic optimal minimum volume for this ultrasound-guided block was 0.075 mL/kg of 0.25% levobupivacaine.[257] Using the traditional fascial-click technique causes erratic needle location in 85% of cases and 45% of blockade failures.[259]

Transversus Abdominis Plane Block

The transversus abdominis plane (TAP) block presents a very interesting alternative to the ilioinguinal and iliohypogastric nerve block for inguinal surgery in children.[260] It has become incredibly popular for analgesia for abdominal wall surgery. One objective of this technique is to block the segmental nerves T9 to T12 (thoracoabdominal nerves) and ilioinguinal and iliohypogastric nerves by spread of local anesthetic in the plane separating the transverse abdominal muscle and internal oblique muscle by a single injection.

Ilioinguinal Nerve Block

- Place a linear probe or a hockey stick probe along the anterior superior iliac spine with the probe oriented towards the umbilicus.

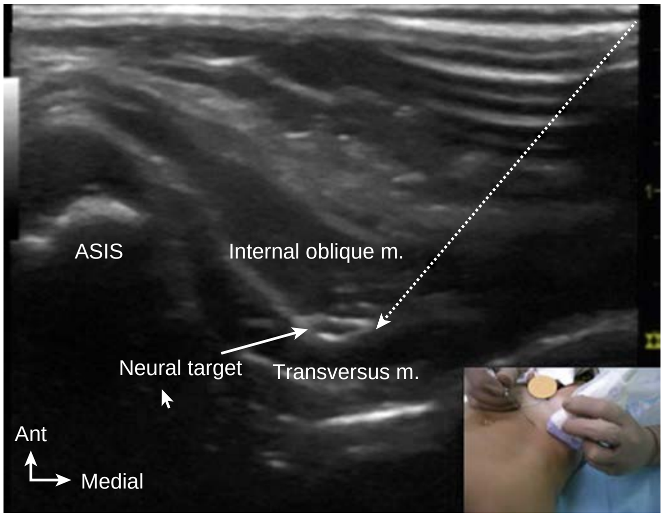

Fig. 76.44 Ultrasound. Ilioinguinal and iliohypogastric block imaging and probe placement for in-plane needle insertion. *ASIS,* Anterior superior iliac spine; *m,* muscle.

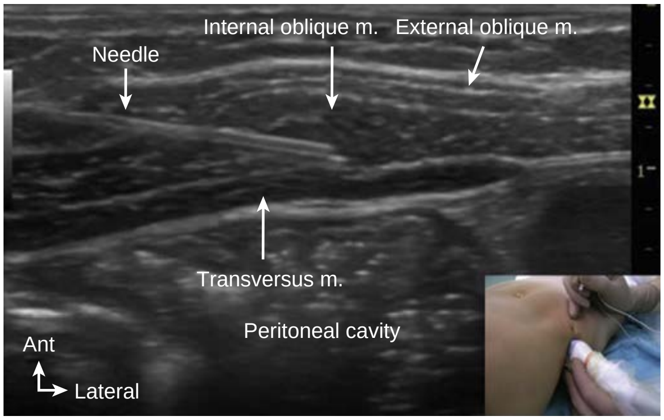

Fig. 76.45 Ultrasound transversus abdominis plane block imaging and probe placement for in-plane needle insertion. *m.,* Muscle.

- The three layers of the abdominal wall muscles can be recognized.
- The ilioinguinal nerve and iliohypogastric nerves are seen as two hypoechoic structures between the internal oblique and transversus abdominis muscles.
- Using an in-plane approach, a 27-gauge needle is advanced and placed between the internal oblique abdominal and the transversus abdominis muscle.
- After aspiration, 0.1mL/kg of local anesthetic solution is injected.

The lumbar triangle of Petit (a space bounded by the iliac crest, latissimus dorsi muscle, and external oblique muscle) is used as a landmark, and a sensation of two "pops" indicates the correct needle position. The first pop occurs after penetration of the fascia of the external oblique muscle, and the second occurs after penetration of the internal oblique muscle. In general, the blind TAP block technique is described as easy to perform and having few complications.

In children, ultrasound guidance to perform this block is recommended. The block is accomplished by positioning the probe on the midclavicular line between the iliac crest and the last rib, allowing a puncture in plane (Fig. 76.45). Ultrasound guidance provides greater safety when performing this block by direct visualization of different muscle planes, the needle and its correct position, and distribution of local anesthetics in this plane.[261] Visualization of different muscle planes is sufficient and does not require identification of neural structures itself. The TAP block has been compared to the ultrasound-guided block and ilioinguinal and iliohypogastric ultrasound-guided block for hernia surgery in children.[262] The ilioinguinal and iliohypogastric block produces better postoperative analgesia, probably due to inefficient blockage of the genital branch of the genitofemoral nerve with the TAP block technique. A large prospective data base has demonstrated that the block is safe in children and has few complications.[263] In addition, pharmacokinetic studies have demonstrated the safety of this block in neonates.[264]

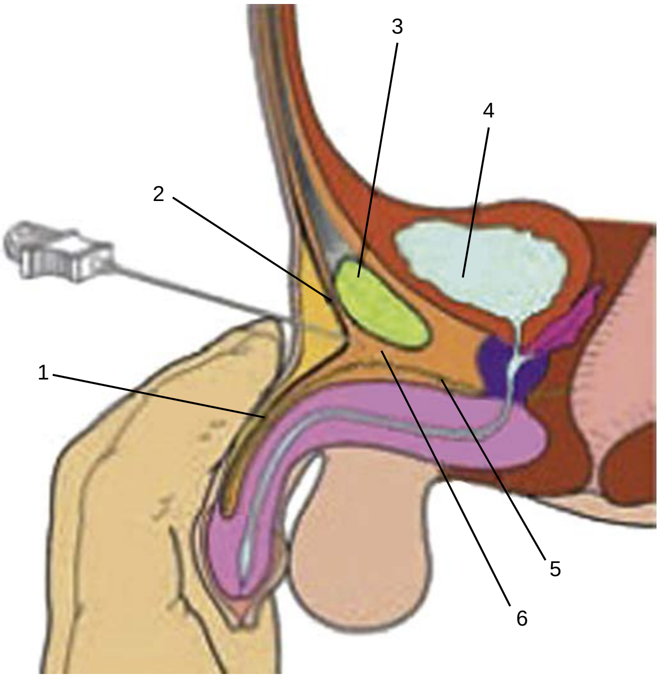

Fig. 76.46 **Anatomic puncture for penile block via the subpubic space.** *1,* Buck fascia; *2,* Scarpa fascia; *3,* pubic bone; *4,* bladder; *5,* dorsal nerve of penis; *6,* subpubic space.

Transversus Abdominis Plane Block

- A high-frequency linear probe or a hockey stick probe is placed lateral to the umbilicus.
- Sliding the probe laterally, the three muscle layers of the abdominal wall are recognized (external and internal oblique abdominal and transverse abdominal).
- In the midaxillary line, using an in-plane approach, place a needle between the internal oblique and the transverse abdominal muscles.
- As local anesthetic is injected, the plane is seen to expand with posterior movement of the transversus abdominis muscle.

PERIPHERAL BLOCKS FOR PENILE SURGERY

Penile Block

Surgery of the prepuce and penis surgery is common in children. This surgery may need advanced pain control for 12 to 24 hours, and is usually done on an outpatient basis. Nerve supply to the penis depends mainly on the dorsal nerve of the penis, which is a terminal branch of the pudendal nerve. The penile block by subpubic approach with long-acting local anesthetic for prolonged analgesia is a good indication for this type of surgery. The usual dose is 0.1 mL/kg (maximum 5 mL) of local anesthetic on each side. The technique is to inject an appropriate volume of local anesthetic in the two compartments of the potential subpubic space behind the Scarpa fascia (Fig. 76.46). Puncture is performed perpendicularly to the skin. Gentle traction is exerted on the penis to tension the Scarpa fascia and better feel the fascial click (Fig. 76.47). This block procedure is easy and its

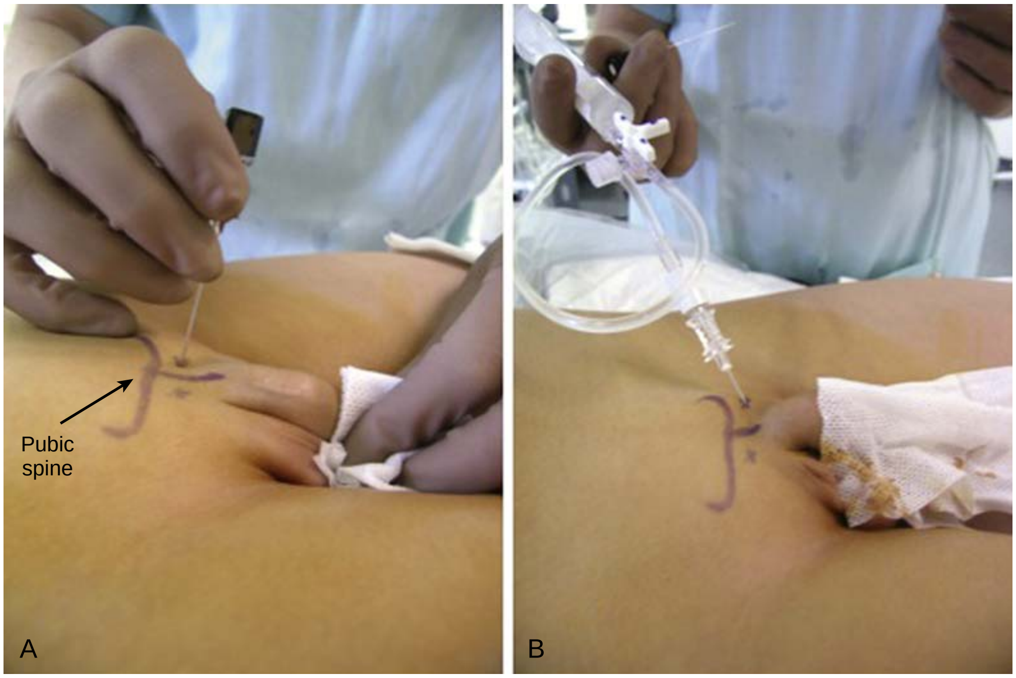

Fig. 76.47 Penile block technique procedure. Gentle traction is exerted on the penis to tension the Scarpa fascia and better feel the fascial click (A). Injection of local anesthetic is easy without resistance (B).

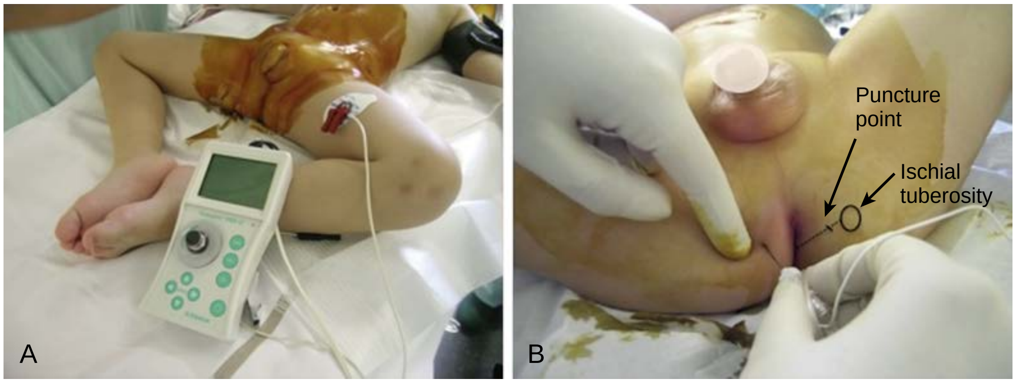

Fig. 76.48 Position for pudendal block procedure (A) and landmarks and puncture (B).

learning curve is particularly short.[265] Ventral injections of the perineal nerve can be combined with dorsal penile nerve block for circumcision surgery to overcome the failure rate of the dorsal nerve block of the penis.

Crossing of the Scarpa fascia also can be verified by ultrasound imaging.[266,267] Ultrasound-guided penile nerve block improved the efficacy of the block in contrast to the fascia-click technique in terms of the postoperative pain during the first postoperative hour and the time to the first requirement for postoperative analgesia.[268]

The morbidity is extremely low (almost nil when a local anesthetic without epinephrine only is used), whereas complications have been reported after attempts to block the nerves by infiltration of a local anesthetic below the Buck fascia at the dorsal part of the penis.

The use of adrenaline and skin infection at the puncture site are the main contraindications to this block. Serious complications are the consequence of a lesion of the dorsal artery in case of median puncture and the risk for injury to the cavernosus corpus with local anesthetic injection equivalent to an intravenous injection of local anesthetic.[269]

The usual indications are elective surgery such as circumcision and phimosis cure or emergency surgery such as reduction of a paraphimosis or release of a foreskin stuck in a zipper pants.

Pudendal Nerve Block

Given the random effectiveness of penile block for surgery of the prepuce in children, some teams advocate the use of pudendal block. The pudendal nerve provides sensory and motor innervation to the pelvic cavity and its contents, including external genital organs. The landmarks are the two ischial tuberosities and anus (Fig. 76.48). The distribution of anesthesia depends on the volume of injectate. With 0.1 mL/kg (up to 5 mL), anesthesia is usually limited to the perineal nerve that supplies the posterior part of the scrotum (this is enough to complement an ilioinguinal, iliohypogastric, and genitofemoral nerve block when a scrotal incision is required). With 0.3 to 0.4 mL/kg on each side (up to 15 mL), all division branches of the pudendal nerve are blocked, thus providing complete analgesia of the perineum, including blockade of the dorsal nerve of the penis.

Because the pudendal nerve is a mixed nerve, a nerve stimulator can be used to locate it more precisely if this is deemed useful (see Fig. 76.48*A*).[256] The expected motor response is a contraction of the external anal sphincter. It is recommended to start at an intensity of 1.5 to 2.0 mA. The position of the needle is considered adequate if the muscle response is obtained for an intensity of between 0.5 and 0.8 mA (0.1-0.2 ms, 1 Hz).

Ultrasound guidance has been used in adults, but identification of the pudendal nerve was possible in only half of the procedures.[270] Because this nerve is accompanied by a terminal artery (pudendal artery), local anesthetics with ephedrine must be avoided.

Naja and associates[271] compared nerve-stimulated pudendal block and dorsal penile nerve block with the fascia-click technique in 60 children undergoing surgery for circumcision. The authors showed a significant decrease in pain scores and analgesic consumption in the group with a pudendal block, with higher parental and surgical satisfaction. Perineal nerves appear to play an important role in the innervation of the penis, and it is the recommended block for circumcision surgery. The perineal and dorsal nerves are terminal branches of the pudendal nerve. The pudendal nerve block has the ability to block the dorsal and perineal nerves with only one single injection.

INTERCOSTAL NERVE BLOCK

Intercostal nerves run along the lower border of each rib, within the intercostal space, a triangular space, with (1) a medial border formed by the posterior intercostal and innermost intercostal muscles, endothoracic fascia, and parietal pleura; (2) a lateral border formed by the internal and external intercostal muscles and intercostal membrane (thickening of the inner fascia of external intercostal muscles); and (3) a base formed by the lower rib. Intercostal nerve block is obtained by injecting a local anesthetic within the intercostal space and, provided several adjacent intercostal spaces are infiltrated, adequate intraoperative and postoperative pain relief is obtained for thoracotomy,[272] liver transplantation, pleural drainage, and management of rib fractures.

This block must be avoided in the presence of impaired oxygenation or gas exchange, and it requires that all patients be kept under intensive medical observation because of the danger of clinically delayed pneumothorax. It is not suitable for outpatient surgery.

The safest approach to the intercostal space is along the midaxillary line with the child lying semiprone using a short 22- or 20-gauge Tuohy needle (intradermal needles are not appropriate) (Fig. 76.49).

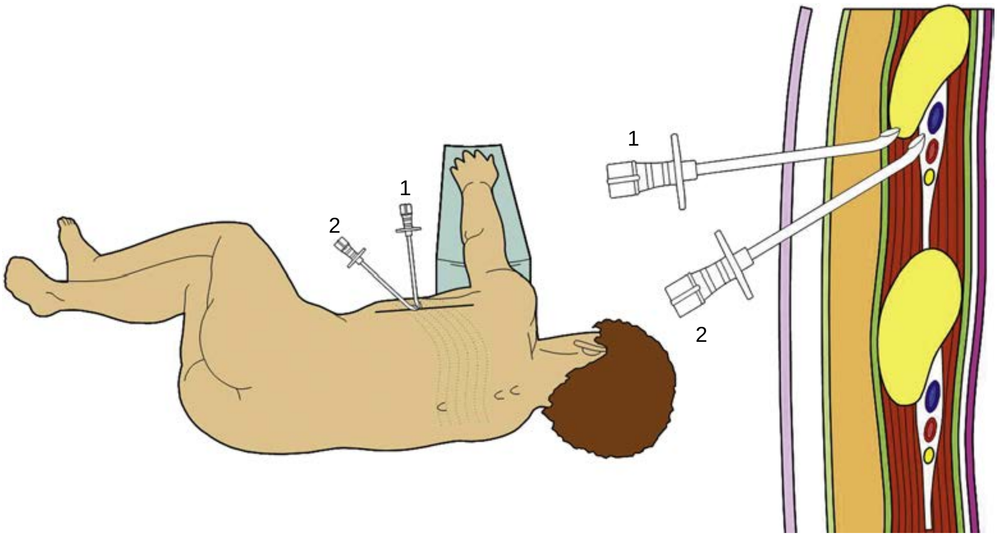

Fig. 76.49 Intercostal nerve block. *1,* Insertion of the needle at an 80-degree angle to the skin; *2,* caudal and dorsal redirection of the needle.

A catheter can be introduced in the intercostal space located at the center of the area to be anesthetized to allow reinjections; the catheter also can be inserted intraoperatively under direct vision by the surgeon.[273,274] However, the safety of continuous techniques is questionable because of high systemic uptake of local anesthetic.[275] Spread of large-volume anesthetic solution can reach distant intercostal spaces (even contralateral ones), probably via the paravertebral space, thus providing adequate duration of pain relief with a single injection in some patients. Spread to the epidural space also can occur. Thus the patient should be admitted to the intensive care unit for careful monitoring of respiratory function and for delayed pneumothorax.

THORACIC PARAVERTEBRAL SPACE BLOCK

Paravertebral block in children was first described in the 1990s[276] and many studies have been done on this block. This technique uses local anesthetic to infiltrate the paravertebral space by a posterior approach, and simultaneously to block several unilateral dermatomes with a single injection, in the manner of a plexus block. A catheter can be introduced into this space to maintain analgesia over an extended period. Paravertebral block will allow a somatic and sympathetic block (sympathetic chain being located in space infiltrated). The dosage is 0.5 mL/kg of long-acting local anesthetic, followed by a continuous infusion of 0.2 to 0.25 mL/kg/h of the same solution.

Anatomic landmarks are the spinous processes of thoracic vertebrae. The puncture site is located parallel to the vertebral axis at the level of the spinous process (Fig. 76.50). The needle must contact the transverse process of a vertebra. The landmarks are defined in children as follows[277]:

- Point of puncture: 10.2 mm + (0.12 × weight in kg) laterally to the spinous process
- Depth of the space: 18.7 mm + (0.48 × weight in kg)

The puncture of the paravertebral space is related to the level of surgery and is usually for a T5 to T6 for thoracotomy surgery and T9 to T10 for subcostal surgery. The LOR method is used to locate the paravertebral space with the Tuohy needle crossing the costotransverse ligament. It is also possible to identify the spinal nerve with nerve stimulation through space at the chosen level. Ultrasound guidance is used to identify the transverse process, the costotransverse ligament, and measure the distance from skin to parietal pleura before performing the block.[278]

Indications for thoracic paravertebral block in children are postoperative analgesia after thoracotomy[279] and upper abdominal surgery with unilateral subcostal incision (kidney surgery, cholecystectomy, splenectomy).[280] This block has been also described for unilateral inguinal hernia repair in children.[281] This block can be used in infants undergoing thoracic surgery for coarctation of aorta or other thoracotomies. Contraindications for this technique are a history of ipsilateral thoracotomy with an increased risk for pneumothorax or parenchymal lung puncture and the deformation of the spinal column, increasing the risk for pleural puncture. This block also must be avoided in cases of serious potential risk for complications (risk for pneumothorax in patients suffering from respiratory diseases with poor gas exchange).

Paravertebral block requires an anesthetist with good technical skills. An alternative to this block is thoracic epidural anesthesia, which has less risk for direct spinal cord injury. This has now become part of the ERAS protocol for children undergoing pectus excavatum repair at Lurie Children's Hospital. (Personal correspondence, SS)

OTHER NERVE BLOCKS OF THE TRUNK

Interpleural (or intrapleural) blocks that consist of injecting a local anesthetic within the pleural cavity without creating a pneumothorax elicited enthusiasm some years ago but was never established in pediatric anesthesia. Other blocks of nerves of the trunk, including paravertebral ganglion, genitofemoral, paracervical (uterosacral), and transsacral nerve blocks, are not used in pediatric patients. More recently there are other blocks introduced in this space including erector spinae blocks and serratus plane blocks. There is no definitive evidence in children for these blocks and their efficacy although we have used them as an alternative for paravertebral blocks in certain settings.

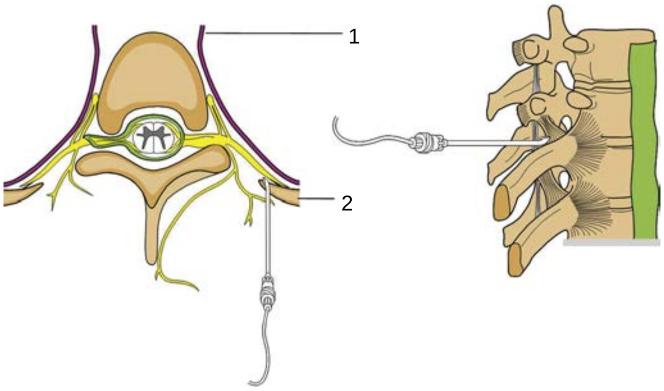

Fig. 76.50 Block of the thoracic paravertebral space. *1,* Parietal pleura; *2,* rib.

ERECTOR SPINAE PLANE BLOCKS

First described in 2016, the erector spinae plane (ESP) block has very recently gained substantial interest and use, with limited but rapidly growing evidence[282] suggesting promise as a safe and effective alternative to neuraxial blocks, including but not limited to paravertebral blocks, for procedures including thoracotomy,[283] pyeloplasties,[284] inguinal hernia repairs,[285] and hip surgery.[286] Single injection, programmed intermittent serial bolus,[287] and continuous catheter[283] routes have all been described, but are limited to case reports and series.

Technique: The erector spinae muscle is visualized lateral to the spine under ultrasound guidance, followed by needle guidance towards the transverse process and hydrodissection of the erector spinae interfascial plane, with injectate spreading cranially and caudally along the continuous plane of the vertebral column. Proposed mechanism is blockade of the dorsal and ventral rami of thoracic spinal nerves and sympathetic nerve fibers, providing somatic and visceral pain control (Fig. 76.51).[282]

This posterior thoracic block presents key advantages of avoiding or decreased risks of dural puncture, potential for bladder catheterization, pneumothorax, or spinal hematoma formation, giving it the potential for use in cardiac procedures with anticoagulation and cardiopulmonary bypass[288] and higher risk patients[289] including pre- and full-term infants.[283,284,290]

Face, Head, and Neck Nerve Blocks

NERVE BLOCK OF THE FACE

All sensory innervation of the face is the trigeminal nerve (fifth cranial nerve, or vagus nerve) associated with the C2 to C4 cervical nerve roots that constitute the superficial cervical plexus.

Anatomic Considerations

The fifth cranial nerve provides sensory and motor components. The sensory component is combined in the trigeminal ganglion (semilunar or gasserian ganglion), which lies in the Meckel cave, an invagination of the dura mater near the apex of the petrous part of the temporal bone in the posterior cranial fossa. Postganglionic fibers exit the ganglion to form three nerves, as follows:

1. The supratrochlear (V1), innervating the forehead, eyebrows, upper eyelids, and anterior area of the nose
2. The maxillary nerve (V2), innervating the lower eyelid, upper lip, lateral portion of the nose and nasal septum, cheek, roof of the mouth, bone, teeth, sinus of the maxilla, and soft and hard palates
3. The mandibular nerve (V3) innervating the anterior two thirds of the tongue and the skin, mucosa, teeth, and the bone of the mandibular.

These terminal sensory nerves can be blocked either at their emergence point from the cranium, as deep procedures (V2 and V3), or more distally when they exit the facial bone as superficial blocks (V1, V2, V3) (Fig. 76.52).

Superficial Trigeminal Nerve Blocks

For superficial trigeminal nerve blocks, the local anesthetic solution should be injected in close proximity to the three individual terminal superficial branches of the trigeminal nerve divisions: the frontal nerve (of ophthalmic nerve, V1 division), infraorbital nerve (of maxillary nerve, V2 division), and mental nerve (sensory terminal branch of mandibular nerve, V3 division). Each nerve is anatomically close to its respective foramen, which is usually on a line perpendicular through the center of the pupil.

Supratrochlear nerve: The supraorbital foramen can be easily palpated by following the orbit rim 2 cm from the midline in adults (union of the medial third and lateral two thirds). The needle (intradermal needle, 25 gauge in adults to 30 gauge in children) is introduced a half centimeter under the inferior edge of the eyebrow and is directed medially and cephalad. When the needle tip is near the supraorbital notch, after test aspiration and with caution to not penetrate the foramen, local anesthetic solution (0.5-1 mL) can be injected, creating a subcutaneous wheal. For supratrochlear block, the landmarks are the top of the angle formed by the eyebrow and the nasal spine where the nerve is in contact with the bone. The supratrochlear nerve can be blocked without removal by directing the needle approximately 1 cm toward the midline and injecting an additional 0.5 mL of local anesthetic.

Infraorbital branch: The terminal branch of the maxillary nerve (second division of the trigeminal nerve) is called the infraorbital nerve when it reaches the infraorbital fossa. The infraorbital artery and vein run parallel in close proximity to the nerve. Its innervation involves the skin and mucous membrane of the upper lip, lower eyelid, and the cheek. Two approaches can be used to perform this block: the intraoral and extraoral approaches. Regardless of the technique, it is necessary to prevent penetration of the foramen and eventual damage of the eyeball by palpating the foramen.

Intraoral approach: For the intraoral approach, the external landmarks include the foramen localized by palpation, the incisor, and the first premolar. The needle (25 or 27 gauge) is inserted at the buccal mucosa in the subsulcal groove at the level of the canine or the first premolar

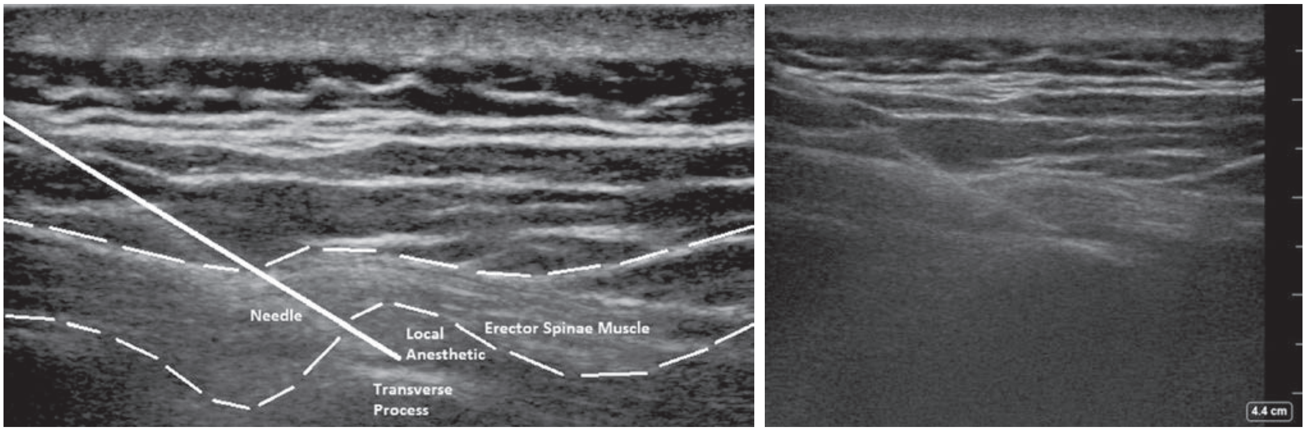

Fig. 76.51 **Erector spinae block.**

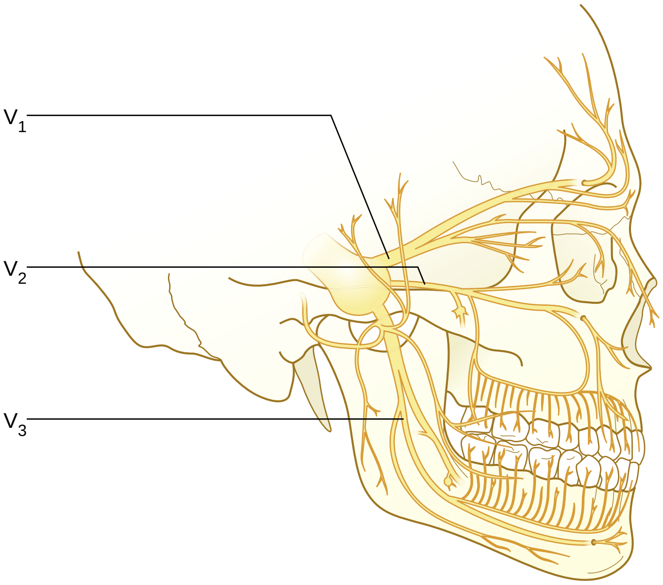

Fig. 76.52 **Facial nerves distribution.**

and directed upward and outward into the canine fossa. A finger is placed over the infraorbital foramen to assess the proper location of the needle tip and avoid damage to the eye.[294]

Extraoral approach: For the extraoral approach, the infraorbital foramen is palpated just below the orbital rim, at the intersection of a vertical line drawn caudally through the center of the pupil and a horizontal line through the alae nasi. The needle (25 or 27 gauge) is advanced perpendicularly with a cephalic and medial direction toward the foramen until bony resistance is met (Fig. 76.53).

The main surgical indication in children is cleft lip repair with good perioperative pain management and a decrease in opioid use.[291-294]

The mental nerve is the terminal branch of the alveolar nerve (the largest branch of the mandibular nerve). It emerges at the mental foramen. The mental foramen is located in line with the pupil on the mental process of the mandible, in regard to the inferior premolar tooth. Puncture is 1 cm lateral to the foramen palpated. The 25- or 27-gauge needle is directed with a lateral-to-medial direction to avoid foramen penetration (Fig. 76.54).

After negative aspiration, 1 to 3 mL of local anesthetic is injected for these different approaches. Complications are hematoma, persistent paresthesia of the innervated territory, prolonged numbness, and intravascular injection.

Ultrasound guidance can be used to locate the foramina for superficial trigeminal nerve blocks.[129] It appears as an easy and safe modality. The ultrasound imaging of foramina is the classic disruption of the bone table (Fig. 76.55).

Suprazygomatic Approach to Maxillary Nerve

The maxillary nerve exits the skull through the foramen rotundum and gives its terminal branches. Except for the middle meningeal nerve, innervating the dura mater, all branches (zygomatic branches, superior alveolar nerve, pterygopalatine and parasympathetic branches, palatine and pharyngeal branches) arise in the pterygopalatine fossa to the face. At the upper part of the pterygopalatine fossa, the maxillary nerve is accessible for a complete maxillary block. The block covers the lower eyelid, ala of the nose, cheek, upper lip, cutaneous zygomatic and temporal zone on the face and superior teeth, palatine zone, and maxillary bone.

The suprazygomatic approach to the maxillary nerve in pterygopalatine fossa seems to be the safest and is easily reproducible in children.[295] The patient is supine, with the head in neutral position or turned slightly to the opposite side. The needle entry point is situated at the angle formed by the superior edge of the zygomatic arch below and the posterior orbital rim forward (Fig. 76.56). The needle (22-25 gauge) is inserted perpendicular to the skin and advanced to reach the greater wing of the sphenoid at a depth of approximately 10 to 15 mm. The needle is then reoriented in a caudal and posterior direction and advanced 35 to 45 mm deep to the pterygopalatine fossa (Fig. 76.57). After a negative aspiration test for blood, 0.15 mL/kg to a maximum of 5 mL of local anesthetic solution is slowly injected.

Ultrasound guidance technique is possible with the ultrasound transducer located in the infrazygomatic area, over the maxilla, with an inclination of 45 degrees in both the frontal and horizontal planes (Fig. 76.58). The probe location allows visualization of the pterygopalatine fossa, limited anteriorly by the maxilla and posteriorly by the greater

wing of the sphenoid. The needle is advanced using an out-of-plane approach. This real-time ultrasound-guided technique is easy and ensures the correct location of local anesthetic injection in the pterygopalatine fossa (Fig. 76.59).[296]

Mandibular Nerve Block

The mandibular nerve, the largest branch of the trigeminal nerve, exits from the cranium through the foramen ovale of the greater wing of the sphenoid. The anterior trunk is formed with branches serving mainly motor innervation to temporalis, masseter, pterygoids, mylohyoid, tensor tympani and palati muscles, and the buccal nerve. Auriculotemporal, lingual, and inferior alveolar nerves comprise the posterior trunk.

The puncture area is bounded by the zygomatic arch at the top and the mandibular notch just anterior to and below the tragus of the ear (Fig. 76.60). The needle entry point is located in the sigmoid fossa between the coronoid and condylar process of the ramus of the mandible. To avoid the risk for arterial puncture, it is recommended to prick as high as possible in the space between the zygomatic arch and the center of mandibular notch (see Fig.

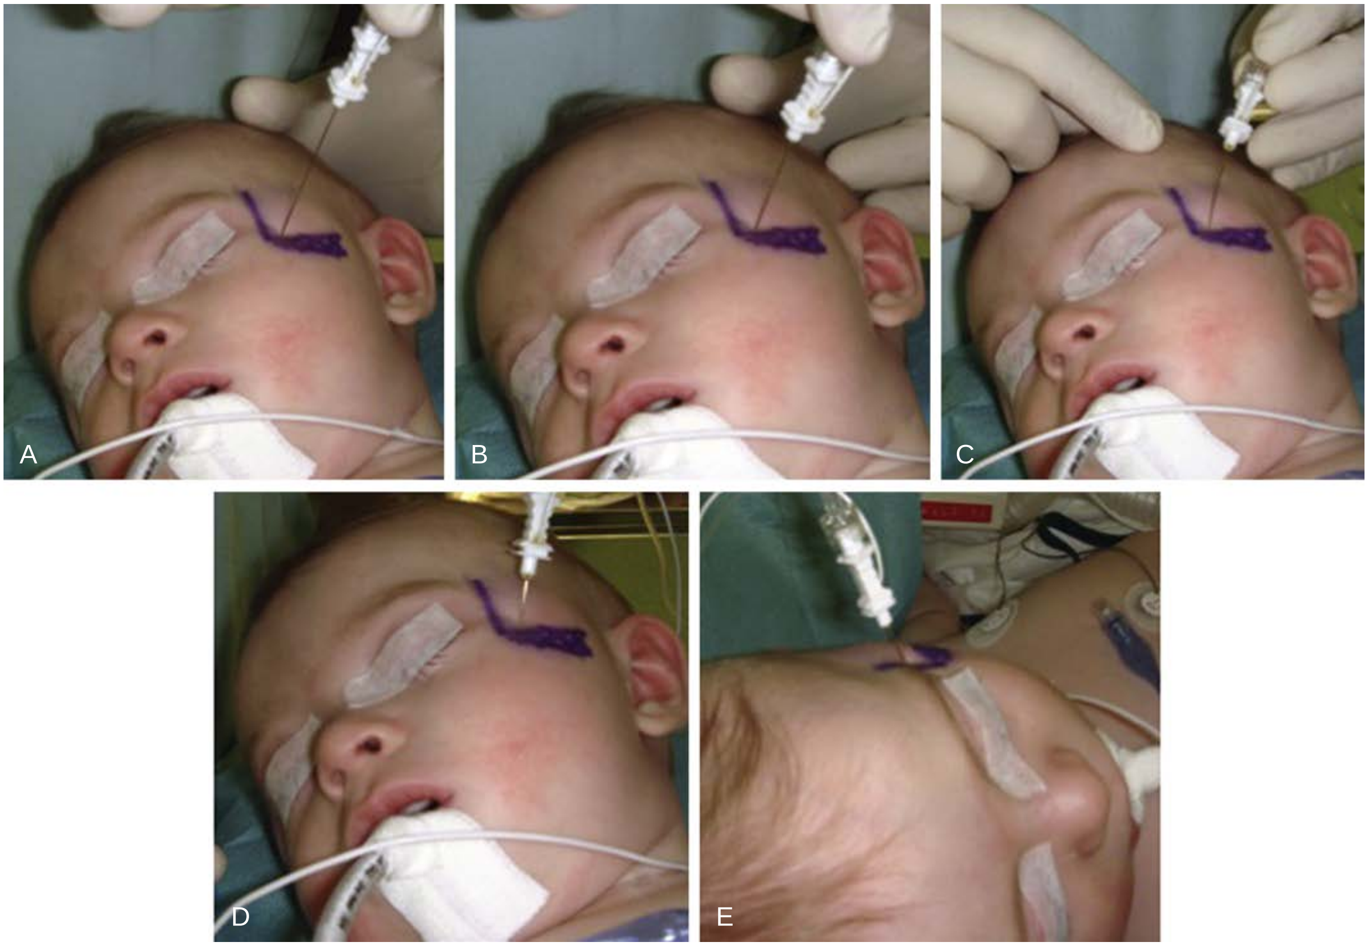

Fig. 76.57 Suprazygomatic maxillary nerve block technique. The needle was inserted perpendicular to the skin (A) and advanced to reach the greater wing of the sphenoid at approximately 10 to 15 mm depth (B). Reorientation of needle in a caudal and posterior direction (C) and advancement of 35 to 45 mm deep to the pterygopalatine fossa (D and E).

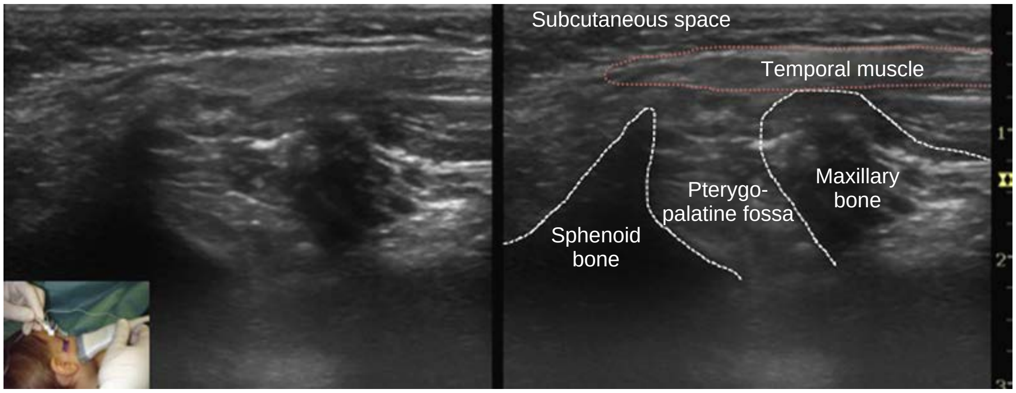

Fig. 76.58 Ultrasound imaging of suprazygomatic maxillary nerve block.

76.60). After perpendicular skin penetration, toward the lateral pterygoid plate (to a distance of 2-4 cm of depth), the needle (22-25 gauge) is advanced posteriorly and inferiorly maintaining the same depth, guided by mandible ascension twitch. The minimal intensity of stimulation (~0.5 mA) is determined, and 0.1 mL/kg to a maximum of 5 mL of local anesthetic solution is slowly injected after negative repeated blood test aspirations. This transcutaneous procedure with nerve stimulation appears easier and has a high success rate.

Block of the Nose: Nasociliary Nerve Block and External Nasal Nerve Block

The innervation of the nose and nasal cavity is quite complex, implicating both the ophthalmic (V1) and maxillary (V2) branches of the trigeminal nerve.

The nasociliary nerve is blocked before its division into nasal branches of the anterior ethmoidal nerve and the infratrochlear nerve, and near the ethmoidal foramen. A 25- or 27-gauge needle is inserted 1 cm above the medial

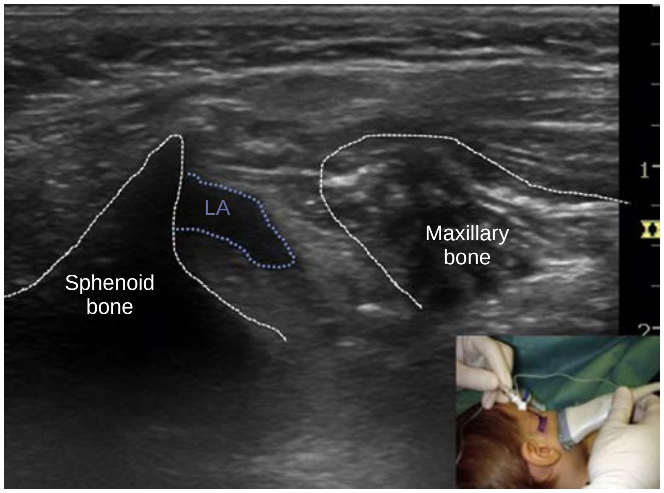

Fig. 76.59 **Ultrasound imaging of suprazygomatic maxillary nerve block with local anesthetic *(LA)* injection.**

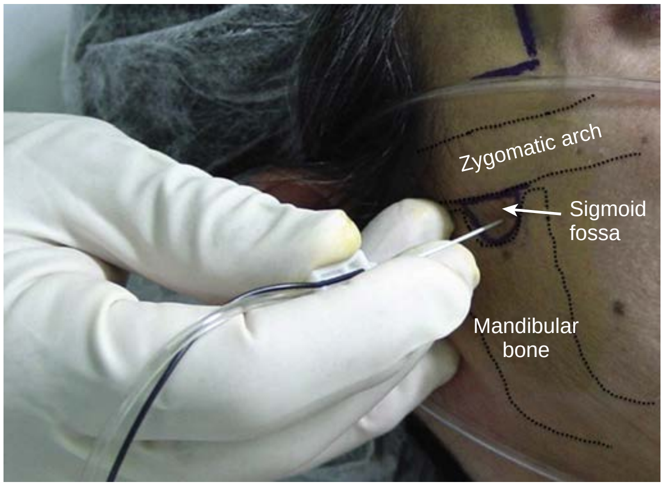

Fig. 76.60 **Mandibular nerve block procedure.**

canthus, halfway between the posterior palpebral fold and the eyebrow. It is then directed medially and backward in contact with the bony roof of the orbit. At a depth of 1.5 cm the needle should be at the anterior ethmoidal foramen, and a maximum of 2 mL of local anesthetic solution is then slowly injected after a negative aspiration test.

The external nasal branch of the anterior ethmoidal nerve can be blocked by infiltration at the junction of nasal bone with cartilage. Combined with infraorbital nerve block, the external nasal nerve block is very effective for perioperative pain control in cleft lip repair.[297]

Nerve Blocks of the External Ear

Anatomic Considerations. The innervation of the pinna of the ear is complex. Both the trigeminal nerve and the cervical plexus mainly provide innervation.

The auriculotemporal branch of the mandibular division of the trigeminal nerve supplies the superior two thirds of the anterior surface. The auriculotemporal nerve passes through the parotid gland to ascend anterior to the auditory canal with the superficial temporal artery and passing superiorly superficial to the zygomatic arch.

The posterior surface of the ear and the lower third of its anterior surface depend on the great auricular nerve and the lesser occipital nerve, two branches of the cervical plexus.

The great auricular nerve arises from the second and third cervical nerve roots, emerges from the posterior border of sternocleidomastoid muscle, and ascends (dividing into anterior and posterior branches) to the mandibular, parotid gland, and pinna. It supplies the lower back of the auricle, the lobule, and the skin of the angle of the mandible (in complement to the mandibular nerve).

The lesser occipital nerve arises from the ventral primary rami of the second and third cervical roots and gives the innervation of the upper part of the ear lobe and lateral occipital zone.

The auricular branch of the vagus nerve (nerve of Arnold) innervates the concha, most of the posterior wall of the external auditory meatus (zona of Ramsay Hunt), and inferior portion of the tympanic membrane.

Regional Anesthesia Techniques. Regional field block around the auricle allows anesthesia of each nerve branch involved in external ear sensory innervation except the Ramsay Hunt area (Fig. 76.61*A*).

The auriculotemporal nerve can be blocked by injecting local anesthetic solution above the posterior portion of the zygoma, anterior to the ear and behind the superficial temporal artery. The needle (27 gauge) is inserted anterior and superior to the tragus. Caution is necessary because of the vicinity of the temporal artery.

The great auricular nerve and the lesser occipital nerves can be blocked distally over the mastoid process posterior to the ear. The needle is inserted behind the lower lobe of the ear and advanced following the curve of the posterior sulcus.

Infiltration with the ring-block technique also provides an additional efficient analgesia of the external ear (see Fig. 76.61*B*).

The superficial cervical plexus block is a widely described proximal approach that anesthetizes two of its terminal branches, the lesser occipital nerve and the great auricular nerve. Several painful procedures of the ear can benefit from this analgesic block, such as incision and drainage of an abscess or hematoma,[298] suture of a large laceration of the ear or the skin surrounding the ear,[299] postauricular incision as in tympanomastoid surgery and cochlear implants,[300] otoplasty,[301] and surgical correction of “bat” ears.[291]

For tympanomastoid surgery, a great auricular nerve block provides good analgesia with reduction of opioid use and a decrease in postoperative nausea and vomiting.[300]

The block of the auricular branch of the vagus nerve is used for pain control after myringotomy and tube placement, tympanoplasty, and paper patch for ruptured tympanic membrane.[286] To perform this block, the tragus is everted, a 30-gauge needle is inserted into the tragus, and, after an aspiration test, 0.2 mL of local anesthetic solution is injected (see Fig. 76.61*C*).

Nerve Block of the Head

Greater Occipital Nerve Block. The greater occipital nerve arises from the second cervical nerve root that emerges between the atlas and the axis. It ascends between the obliquus capitis inferior and semispinalis capitis before piercing the latter muscle. It then becomes subcutaneous by piercing the trapezius aponeurosis, slightly inferior to the superior

nuchal line. At this point, the greater occipital nerve is most often located immediately medial to the occipital artery. The greater occipital nerve provides cutaneous innervation to a major portion of the posterior scalp from the level of the external occipital protuberance to the vertex.

The landmarks to perform the greater occipital nerve block are located at approximately two thirds of the distance on a line drawn from the center of the mastoid to the external occipital protuberance along the superior nuchal line, where it lies medial to the occipital artery. The pulsation of the occipital artery is easy to palpate. Palpation in this area may elicit a paresthesia or uncomfortable feeling in the distribution of the nerve. Usually a 25- or 27-gauge needle can be used depending on the size of the patient. The needle is directed at a 90-degree angle toward the occiput and, after aspiration, 1 to 3 mL of local anesthetic is injected. When the needle is withdrawn, pressure should be maintained over the site of injection to promote the nerve impregnation and to achieve hemostasis. Numbness over the top of the head, after the injection, is a sign of a successful greater occipital nerve block.

An ultrasound-guided technique of greater occipital nerve block has been described recently with good visualization of the nerve. The nerve can be easily visualized between the obliquus capitis inferior and the semispinalis capitis muscle; the pulsation of the occipital artery can be seen close to the nerve in this position. This technique is preferred for precision and safety of performing this block.[302]

Scalp Blocks. The scalp block is classically described with potential blockade of seven nerves, including branches from cervical spinal rami and from trigeminal division.

The greater occipital, lesser occipital, and great auricular nerves originate from ventral and dorsal rami of C2 and C3 spinal nerves. The greater occipital nerve travels up to the vertex, and the lesser occipital nerve innervates skin behind the ear.

The ophthalmic division of trigeminal nerve gives off, by the frontal nerve, supraorbital and supratrochlear nerves that innervate the skin from the forehead to the lambdoidal suture.

The zygomaticotemporal nerve is one of the two branches of the zygomatic nerve that arises from the maxillary division of the trigeminal nerve. It innervates a small area of the forehead and temporal area.

The auriculotemporal nerve arises from the mandibular division of the trigeminal nerve. It innervates the posterior portion of the skin of the temple.

Scalp block is used in adults and children for a variety of head and neck procedures and in neurosurgery or chronic pain diagnostic and therapeutic management (many headache disorders of muscular and nervous etiology). Common reasons for providing anesthesia to the scalp are repair of a laceration, foreign body removal, exploration of scalp wounds, and drainage of abscesses or subdural hematomas. We have used this for performing wake craniotomies.

Most of the time, infiltrative anesthesia is used to perform scalp blocks. All the nerves involved in the scalp's sensitivity become superficial and accessible to the anesthetic. To block the entire scalp, a circumferential infiltration of local anesthetic solution (with 1:200,000 epinephrine), above an imaginary line drawn from the occipital protuberance to the eyebrows, passing along the upper border of the ear, is necessary. Approximately 30 mL is required to perform this ring block around the scalp.

The most common complications associated with scalp anesthesia are hematoma formation at the site of injection and the risk for intravascular injection.

Nerve Block of the Neck

Cervical Plexus Block. Cervical plexus blocks have few but specific indications in pediatric surgery—cervical lymph node biopsy, excision of thyroid nodules,[303,304] and surgery of vocal cords.[305] Only the superficial branches are blocked by a subcutaneous infiltration along the lateral border of the sternocleidomastoid muscle.

Laryngeal Nerve Block. Laryngeal nerve blocks can be used for short-duration laryngoscopic examinations in conscious patients or to facilitate awake intubation when difficult intubation is suspected. It also can be used

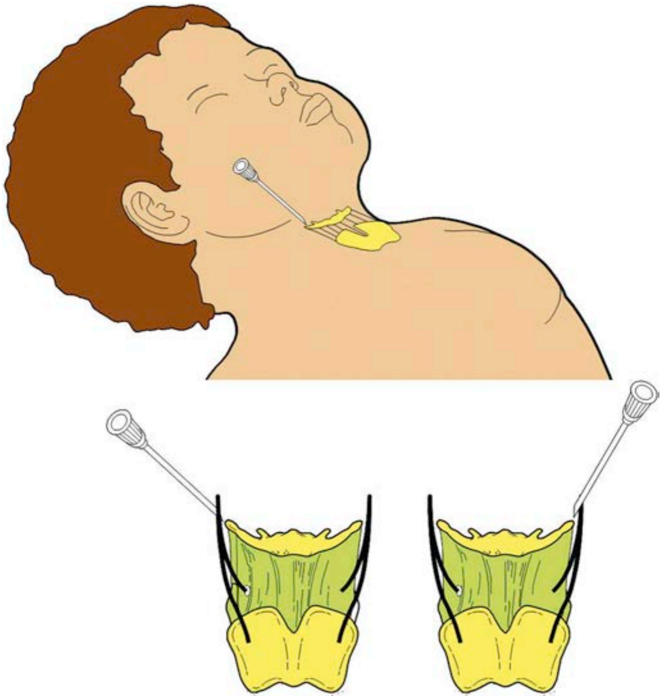

Fig. 76.62 **Laryngeal nerve block.**

to prevent or treat laryngospasm.[306] Several techniques have been described, but the easiest consists of subcutaneous injection of a local anesthetic just lateral to the dorsal ending of the hyoid horns (on each side) (Fig. 76.62). A 27-gauge intradermal needle is inserted close to the hyoid horn ending until contact is made with cartilage. The needle is then slightly withdrawn and 0.1 to 0.2 mL/kg (up to a maximum of 8 mL) of 1% lidocaine is injected subcutaneously. Excellent laryngeal block is usually obtained.

Cervicothoracic (Stellate) Ganglion Block. Stellate ganglion block is a rather dangerous procedure with very few but very specific indications in children: (1) ventricular tachyarrhythmia resulting from congenital long-QT syndrome[307,308] (a left stellate block is recommended) and (2) severe ipsilateral circulatory disorders of the upper extremity. Patients with certain acute pain syndromes such as herpes zoster ophthalmicus[77] or rare chronic pain syndromes such as sympathetically maintained pain syndrome[309,310] may benefit from the technique. This can be performed with the use of US guidance easily. The longus colli muscle is identified; the local anesthetic is injected superior to the longus colli muscle. A Horner's syndrome is verification of correct placement of the block.

Other Procedures

INTRAVENOUS REGIONAL ANESTHESIA

Intravenous regional anesthesia (Bier block) has never been very popular in pediatric anesthesia. Currently, the technique is outdated, even though it is still used in some institutions mainly for fracture repairs (often in emergency departments).[311-313] The technique is the same as in adults. The limb is exsanguinated by an Esmarch bandage or simple gravitation. A tourniquet is placed around the proximal part of the arm and inflated at two to three times the systolic pressure before the Esmarch bandage is removed and 1 mL/kg of 0.5% lidocaine (not exceeding 3 mg/kg) is injected. Prilocaine can be used instead in adolescents. Children tolerate the pain produced by the inflated tourniquet very poorly, and this technique was responsible for several deaths in the past.

Intradermal Wheals

Intradermal wheals are routinely used in adult patients to anesthetize the skin covering deeper structures to be approached. The technique is used less often in children, except for anesthetizing the puncture site of a regional block procedure in nonanesthetized children. It consists of inserting a 25-, 27-, or 30-gauge interdermal needle almost tangentially to the skin, with the bevel facing downward, without penetrating the subcutaneous layers. A small amount (<0.5 mL) of local anesthetic (0.5%-1% lidocaine or prilocaine, with or without epinephrine) is then injected. The skin covering the wheal looks like an orange peel and almost immediate anesthesia of the relevant area is obtained. The only drawback of this technique is that the injection is moderately painful.

Wound Infiltration

In adults, some studies have shown benefits of continuous wound catheters.[314,315] Today, publications on continuous wound catheters in children are limited. Ouaki and coworkers[316] evaluated continuous infusion of ropivacaine through an iliac crest catheter for bone graft postoperative pain relief in children undergoing a maxillary alveolar graft. The catheters were placed close to the iliac periosteal bone at the donor site and infused with 0.125 mL/kg/h of 0.2% ropivacaine for 48 hours with a disposable elastomeric pump. The findings of Ouaki and coworkers showed optimal pain relief with a low pain score and a decrease of chronic pain symptoms after 3 months in contrast to reports in the literature.

In their study, Dashow and associates[317] placed a bupivacaine-soaked absorbable sponge in addition to peri-incisional bupivacaine infiltration at the anterior iliac crest donor site for the management of postoperative pain in children. Their results showed that this regional anesthesia method significantly reduced the postoperative pain score, pain medication requirement, and length of hospital stay.

Precautions must be taken to avoid bacterial contamination and overdosage, especially in cases with extensive wounds or reinjections.

Acknowledgment

The editors and publisher would like to thank Drs. Christophe Dadure, Chrystelle Sola, Bernard Dalens, and Xavier Capdevila for contributing a chapter on this topic in the prior edition of this work. It has served as the foundation for the current chapter.

The authors would like to thank John Hajduk for his help with copyediting the manuscript.

Pediatric Anesthesia

LASZLO VUTSKITS and ANDREW DAVIDSON

KEY POINTS

- At birth the circulation undergoes a fundamental change as blood oxygenation occurs through the lungs rather than the placenta. This transition places some newborns at risk of sudden increases in pulmonary artery pressure with resultant shunting of blood past the lungs through a patent foramen ovale or the ductus arteriosus. This may be triggered by hypoxia, hypercapnia, acidosis, and infection.
- The reduced cellular mass of the neonatal heart devoted to contractility results in less compliant ventricles. This leads to a sensitivity to excessive intravascular volume, poor tolerance to increases in afterload (i.e., the development of biventricular failure), and compared to older children, a relatively rate-dependent cardiac output. In addition, the reduced cardiac calcium stores produce increased susceptibility to myocardial depression by potent anesthetics and also make neonates dependent on exogenous (i.e., blood-ionized) calcium values and vulnerable to the negative inotropic effects of ionized hypocalcemia.
- The neonatal airway differs from the adult airway in four ways: the larynx is located higher in the neck, the glottis is shaped differently and angled over the laryngeal inlet, the vocal cords are angled with the narrowest portion in the subglottic region at the level of the cricoid cartilage.
- Neonates have relatively larger volumes of distribution and lower clearances for most drugs. Thus loading doses generally have to be relatively larger whereas continuous infusion rates or dose intervals tend to be longer. Allometric scaling (e.g., body mass) can predict the dose requirement for most drugs in children better than simple mg/kg calculations.
- The minimum alveolar concentration (MAC) of volatile anesthetic agents is higher in children compared to adults. However, for most agents the MAC in neonates is lower than for older children. Infants achieve more rapid equilibration of inspired-to-tissue concentrations of volatile agents compared to older agents, and hence relative overdose is a risk if higher concentrations are used for prolonged periods of time.
- Neonates and infants are at greater risk of anesthesia-related cardiac arrest compared to older children. The etiology is most commonly related to cardiac or respiratory effects.
- Former preterm infants are at risk for postoperative apnea. The use of regional anesthesia in these children may reduce the incidence of immediate postanesthesia apnea, but ongoing monitoring of the preterm infant is critically important.
- Neonates and infants require adequate analgesia for painful procedures. The optimal dose of general anesthetics to achieve adequate analgesia is unclear in this population. Adult-derived electroencephalograph (EEG) algorithms such as bispectral index (BIS) cannot be used in this age group to guide anesthesia.
- Temperature regulation is especially important for neonates and infants. Because of the large body surface-to-weight ratio, they are vulnerable to intraoperative hypothermia. Efforts to maintain a warm surgical unit through the use of warming devices such as hot air mattresses, application of warm surgical skin preparation solutions, and transport of the neonate or infant in an appropriate transport device, as well as keeping the infant covered during transport, all help prevent hypothermia.
- Compared to adults, children are more susceptible to iatrogenic hyponatremia and subsequent significant morbidity. To minimize this risk, perioperative fluid therapy should consist of an isotonic solution. The classic 4-2-1 rule of Holliday and Segar overestimates the replacement requirement.
- Preschool children are at risk of postoperative delirium and/or agitation. Agitation may be due to many factors including pain, fear, and hunger. Delirium may also cause agitation. Children manifest delirium by becoming inconsolable and not interacting with their parents or caregivers. Many strategies are known to reduce the risk of delirium. A number of approaches have been used to minimize postoperative delirium. Children receiving propofol anesthesia are at lower risk for delirium than those receiving volatile anesthetics.
- Most general anesthetics cause morphologic changes to the developing brain, based on animal studies. Accelerated neuronal apoptosis is the most widely described change. Some human studies have found an association between exposure to anesthesia and surgery in early childhood and subsequent neurodevelopmental issues. This may be explained by a number of confounding factors. At the same time, increasing evidence suggests that an hour of anesthesia in infancy does not have a lasting impact on cognition and a range of other psychometric outcomes.
- Pediatric anesthesia requires appropriate pediatric equipment in a range of sizes. Neonates require ventilators that are designed to meet their needs.
- Preoperative anxiety is common in children. Distraction techniques, premedication with midazolam or α_2 agonists, and parental presence at induction have all been shown to reduce anxiety.

Physiologic Considerations

During development there are substantial changes in a child's physiology and anatomy. Understanding these is key to providing safe pediatric anesthesia care. The most substantial changes occur at birth and in early infancy; however, many systems continue to develop throughout childhood.

INTRAUTERINE DEVELOPMENT

Intrauterine development extends from conception to birth. This prenatal period is characterized by increased vulnerability to a large variety of genetic and external factors that can induce permanent organ dysfunction of variable severity (Table 77.1). Identification of these prenatal risk factors is of utmost importance since they can have a major impact on perioperative management. Prenatal development is usually divided into three stages: (1) the germinal, (2) the embryonic, and (3) the fetal stage. The germinal stage starts with conception and ends approximately 2 weeks later with the implantation of the embryo into the uterine wall. One key feature of this period is the formation of the placenta. Factors, either genetic or environmental, that interfere with the implantation process lead to the termination of pregnancy. The embryonic stage comprises the period between the third and eighth weeks of pregnancy and is characterized by intense cell proliferation, migration, and differentiation leading to the establishment of all major organs. Increased vulnerability to a wide variety of substrates, commonly called teratogens, during this period can induce major developmental defects, many of them incompatible with life. The fetal stage lasts from the ninth week of pregnancy to birth and is characterized by the growth and functional differentiation of organs formed during the embryonic period. Numerous exogenous factors, such as environmental toxins, ionizing radiation, and maternal infections as well as a multitude of drugs can interfere with the physiological patterns of organ development throughout the fetal period which, in turn, will result in organ dysfunction of variable severity. Careful evaluation of prenatal history is therefore an important part of preoperative assessment and can guide further investigations prior to perioperative management.

While pregnancy is considered to reach full term between the completion of the 37th and the 42nd weeks of gestation, fetuses reach an age of viability that may be considered, under tight medical support, as compatible with extrauterine life between the 22nd and 26th weeks after conception. Prematurity is stratified into mild preterm (32-37 weeks), very preterm (28-31 weeks) and extremely preterm (<28 weeks) periods with increasing neonatal morbidity and mortality based on degree of prematurity (Fig. 77.1).[1]

Normal birth weight at term is 2500 g to 4200 g. Infants weighing less than these norms can be classified as low birth weight (<2500 g), very low birth weight (<1500 g), and extremely low birth weight (<1000 g). Plotting weight against gestational age allows further classification into three additional categories: small for gestational age, appropriate for gestational age, or large for gestational age (see Fig. 77.1). Infants who are small or large for gestational age often have developmental problems or difficulties associated with maternal disease which can directly affect perioperative care (see Table 77.1).

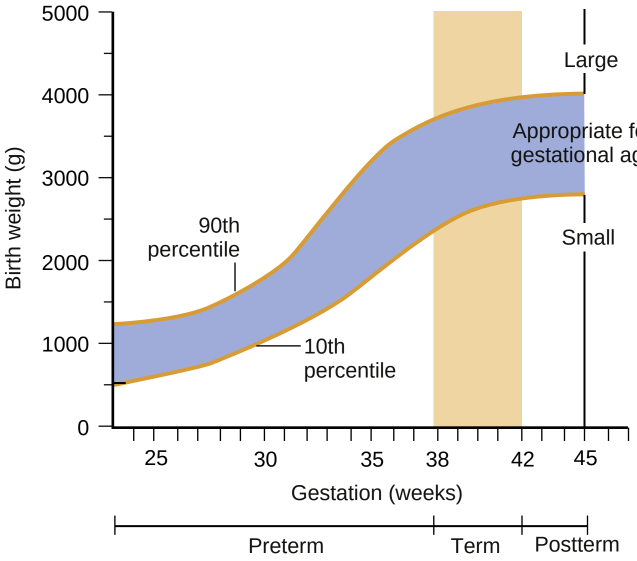

Fig. 77.1 Plotting birth weight against gestational age for neonates determines whether infants are small, appropriate, or large for gestational age. Babies who are either small or large for gestational age are particularly likely to have a variety of problems such as metabolic, developmental, infectious, or structural abnormalities, as well as drug addiction and withdrawal. (Modified from Battaglia FC. Intrauterine growth retardation. *Am J Obstet Gynecol.* 1970;106:1103–1114. Used with permission.)

NEONATAL AND INFANT PHYSIOLOGY

The physiology of fetal life is fundamentally different from that of the neonate. The transition from intra- to extrauterine life is rapid and involves a complex and well-orchestrated series of events aimed to ensure neonatal viability.[2] A clinically useful measure to assess the condition of the newborn infant immediately after birth is the Apgar score (Table 77.2) This score is reported at 1 minutes and 5 minutes after birth for all infants and can be extended thereafter to follow fetal to neonatal transition. Apgar scores between 7 and 10 are considered reassuring, a score of 4 to 6 as moderately abnormal, while scores 3 and below are usually indicative of poor outcome.[3] It is, nevertheless, important to note that the Apgar score has its limitations and cannot be used alone to diagnose neonatal asphyxia.[3]

Cardiovascular System

The cardiovascular system undergoes dramatic physiologic and maturational changes during the first year of life. In utero, most of the cardiac output is directed from the placenta across the foramen ovale into the ascending aorta (oxygenated blood), whereas superior vena cava blood (deoxygenated) is directed to both the pulmonary artery and the ductus arteriosus (see also Chapter 78).[2] This pattern of circulation results in minimal

TABLE 77.1 Common Neonatal Problems Associated With Weight and Gestational Age

Gestation	Relative Weight	Neonatal Problems at Increased Incidence
Preterm (<37 weeks)	SGA	Respiratory distress syndrome Apnea Perinatal depression Hypoglycemia Polycythemia Hypocalcemia Hypomagnesemia Hyperbilirubinemia Viral infection Thrombocytopenia Congenital anomalies Maternal drug addiction Fetal alcohol syndrome
	AGA	Respiratory distress syndrome Apnea Hypoglycemia Hypocalcemia Hypomagnesemia Hyperbilirubinemia
	LGA	Respiratory distress syndrome Hypoglycemia; infant of diabetic mother Apnea Hypoglycemia Hypocalcemia Hyperbilirubinemia
Normal (37-42 weeks)	SGA	Congenital anomalies Viral infection Thrombocytopenia Fetal alcohol syndrome Perinatal depression Hypoglycemia
	AGA	—
	LGA	Birth trauma Hyperbilirubinemia Hypoglycemia; infant of diabetic mother
Postmature (>42 weeks)	SGA	Meconium aspiration syndrome Congenital anomalies Viral infection Thrombocytopenia Maternal drug addiction Perinatal depression Aspiration pneumonia Hypoglycemia
	AGA	—
	LGA	Birth trauma Hyperbilirubinemia Hypoglycemia; infant of diabetic mother

AGA, Appropriate for gestational age; *LGA,* large for gestational age; *SGA,* small for gestational age.

intrauterine pulmonary blood flow. At birth, a number of events change hemodynamic interactions such that the fetal circulation adapts to the postuterine environment. Specifically, the placenta is removed from the circulation; portal blood pressure falls, which causes the ductus venosus to close; and blood becomes oxygenated through the lungs. Exposure of the ductus arteriosus to oxygenated blood induces ductal closure. As a result of the combined effects of lung expansion, exposure of blood to oxygen, and loss of low resistance through placental blood flow, pulmonary vascular resistance decreases while peripheral vascular resistance rapidly rises. The decrease in pulmonary vascular resistance occurs on the first day of life and continues to decrease gradually during the next several years as the architecture of the pulmonary vessels changes. An increase in pressure on the left side of the heart (caused by the increase in peripheral vascular resistance) induces mechanical closure of the foramen ovale. As a result, all three connections between the right and left sides of the circulation close. Although closure of the ductus arteriosus probably occurs primarily from an increase in arterial oxygen concentration, successful completion requires arterial muscular tissue; that such tissue is less prevalent in preterm infants may

TABLE 77.2 The Apgar Score

Score	0 Points	1 Point	2 Points
Appearance (skin color)	Cyanotic/pale all over	Peripheral cyanosis only	Pink
Pulse (heart rate)	0	<100	100-140
Grimace (reflex irritability)	No response to stimulation	Grimace (facial movement)/weak cry when stimulated	Cry when stimulated
Activity (tone)	Floppy	Some flexion	Well flexed and resisting extension
Respiration	Apneic	Slow, regular breathing	Strong cry

partly account for the frequent incidence of patent ductus arteriosus in preterm infants. True mechanical closure of the ductus by fibrosis does not occur until 2 to 3 weeks of age.

During this critical period, the infant can readily revert from the adult type of circulation to a fetal type of circulation; this state is called *transitional circulation*. Many factors (e.g., hypoxia, hypercapnia, anesthesia-induced changes in peripheral or pulmonary vascular tone) can affect this precarious balance and result in a sudden return to the fetal circulation. When such a *flip-flop* occurs, pulmonary artery pressure increases to systemic levels, blood is shunted past the lungs via the patent foramen ovale, and the ductus arteriosus may reopen and allow blood to shunt at the ductal level. A rapid downhill spiral may occur and lead to severe hypoxemia. In this situation, the hypoxemia may be prolonged, despite adequate pulmonary ventilation with 100% oxygen. In most cases, simple hyperventilation with resultant reduction in arterial partial pressure of carbon dioxide ($PaCO_2$) will cause the pulmonary artery pressure to return to normal.

Risk factors increasing the likelihood of prolonged transitional circulation include prematurity, infection, acidosis, pulmonary disease resulting in hypercapnia or hypoxemia (aspiration of meconium), hypothermia, and congenital heart disease. Care must be directed to keeping the infant warm, maintaining normal arterial oxygen and carbon dioxide tensions, and minimizing the effects of anesthetic-induced myocardial depression for those newborns requiring anesthesia.

The myocardial structure of the heart, particularly the volume of cellular mass devoted to contractility, is significantly less developed in neonates than in adults. This difference, as well as developmental changes in contractile proteins, produce a leftward displacement of the cardiac function curve and less compliant ventricles. As a result of these differences, cardiac output is strongly dependent on heart rate; bradycardia is poorly tolerated because the infant cannot easily compensate for the decreased heart rate by increasing stroke volume to maintain normal cardiac output.

The most frequently encountered arrhythmia in pediatric populations is hypoxia-induced bradycardia that can lead to asystole, if not appropriately handled. Ventricular fibrillation is extremely rare in infants and children.

Generally, myocardial function is usually adequate in most infants and children including those with congenital heart disease. Rare exceptions from this rule are individuals with congenital neuromuscular and metabolic diseases where the myocardium can be seriously compromised.[4] In neonates and infants, cardiac calcium stores are reduced because of the immaturity of the sarcoplasmic reticulum; consequently, these populations have a greater dependence on exogenous (blood-ionized) calcium and probably increased susceptibility to myocardial depression by volatile anesthetics that have calcium channel–blocking activity.

Respiratory System

The pulmonary system is not capable of sustaining life until both the lungs and the vascular system have sufficiently matured to allow the exchange of oxygen from air to the bloodstream across the pulmonary alveolar-vascular bed. The lung bud septates from the foregut during the first trimester and the gas exchanging portions of the airway are formed during the second trimester. Alveolar ductal development starts at gestation week 24 while the septation of the air sacs begins around gestational week 36.[5] Alveoli then increase in number and size until a child is approximately 8 years old. Further growth is manifested as an increase in size of the alveoli and airways. At term, complete development of surface-active proteins helps maintain patency of the airways. If a child is prematurely born and these proteins are insufficient, then respiratory failure (e.g., respiratory distress syndrome) may occur.

Respiration is less efficient in infants than adults. The airway of infants is highly compliant and poorly supported by the surrounding structures. The chest wall is also highly compliant; therefore the ribs provide little support for the lungs; that is, negative intrathoracic pressure is poorly maintained. The small diameter of the airways increases resistance to airflow. Thus functional airway closure accompanies each breath. Dead space ventilation is proportionally similar to that in adults; however, oxygen consumption is two to three times higher. In preterm infants, the work of breathing is approximately three times that of adults. This increased work of breathing can increase significantly by cold stress (i.e., increased metabolic demand for oxygen) or any degree of airway obstruction. Another important factor is the composition of the diaphragmatic and intercostal muscles. These muscles do not achieve the adult configuration of type I muscle fibers until the child is approximately 2 years old (Fig. 77.2).[6] Because type I muscle fibers provide the ability to perform repeated exercise, any factor that increases the work of breathing contributes to early fatigue of the respiratory muscles of infants; this partially explains why the infant's respiratory rate and hemoglobin desaturation is so rapid, and their propensity to develop fatigue and apnea with airway obstruction.

Differences in airway anatomy explain the more likely potential for technical airway difficulties in infants than in teenagers or adults. Typically, the airway of infants differs from adults in five ways[7,8]: (1) The relatively large size of the infant's tongue, in relation to the oropharynx, suggests that the infant is more likely to sustain airway obstruction and technical difficulties during induction of anesthesia and laryngoscopy. Recently, however, magnetic resonance imaging (MRI) studies have called this into question by showing that soft tissues surrounding the upper airway grow proportionally to the skeletal structures during childhood.[9] (2) Other anatomic differences may account for some of the airway management challenges in children. The larynx is located higher (more cephalic) in the neck, thus making straight blades more useful than curved blades. (3) The epiglottis is shaped differently, being short, stubby, omega shaped, and angled over the laryngeal inlet. Control with the laryngoscope blade is therefore more difficult. (4) The vocal cords are angled; consequently, a *blindly* passed tracheal tube may easily lodge in the anterior commissure rather than slide into the trachea. (5) Finally, the infant larynx is funnel shaped, the narrowest portion occurring at the cricoid cartilage (Fig. 77.3).[8] While classic teaching is that the adult larynx is cylindrical and the infant larynx is funnel shaped, it is now recognized that the narrowest portion of the airway in approximately 70% of adults is also in the same subglottic region at the level of the cricoid cartilage as it is in children. Nonetheless, the challenges of tracheal tube placement in children are different than they are in adults. For adult patients, the airway size is much larger, so the commonly used tracheal tubes are usually easy to advance past the glottic opening.[10] In infants or young children, a tracheal tube that easily passes the vocal cords may be tight in the subglottic region because of the relatively greater proportional narrowing at the level of the cricoid cartilage.

Although neonates and infants are considered as obligate nasal breathers, they can also utilize the oral airway to maintain ventilation both spontaneously and in response to complete nasal obstruction.[11] Even in preterm infants, the prevalence of spontaneous oral breathing has been reported to be as high as 50% during sleep, and oral breathing could be consistently initiated in this population upon nasal obstruction.[12,13]

The Kidneys

Renal function is diminished in neonates with even less function in preterm infants as a result of lower renal perfusion pressures and immature glomerular and tubular function (Table 77.3) (Fig. 77.4).[14,15] In full-term infants, maturation of glomerular filtration and tubular function is nearly complete by approximately 20 weeks after birth, although delayed in preterm infants. Complete maturation of renal function occurs at approximately 2 years of age. As a result of the delayed development, newborns have reduced ability to excrete free water and solute loads; the half-life of medications excreted by means of glomerular filtration will be prolonged (e.g., antibiotics). Dosing intervals should be longer in neonates.

The Liver

At term, the functional maturity of the liver is incomplete.[16,17] Most enzyme systems for drug metabolism are developed, but not yet induced (stimulated) by the material that they metabolize. As the infant grows, the ability to

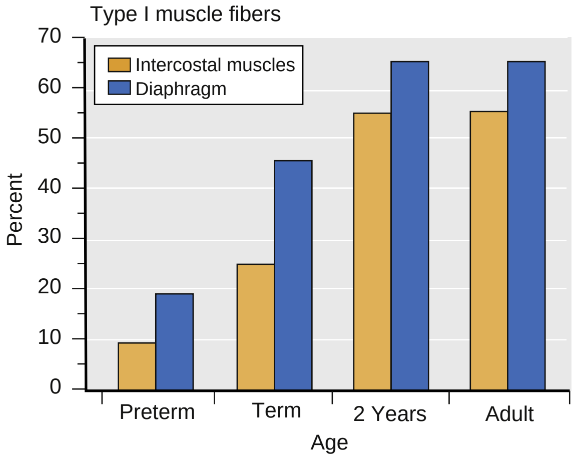

Fig. 77.2 The composition of the diaphragm and intercostal muscles significantly changes during the first 2 years of life. The number of type I muscle fibers is inversely related to age and may account, in part, for the ease of inducing respiratory fatigue as the work of breathing increases. (Data from Keens TG, Bryan AC, Levison H, et al. Developmental pattern of muscle fiber types in human ventilatory muscles. *J Appl Physiol.* 1978;44:909–913.)

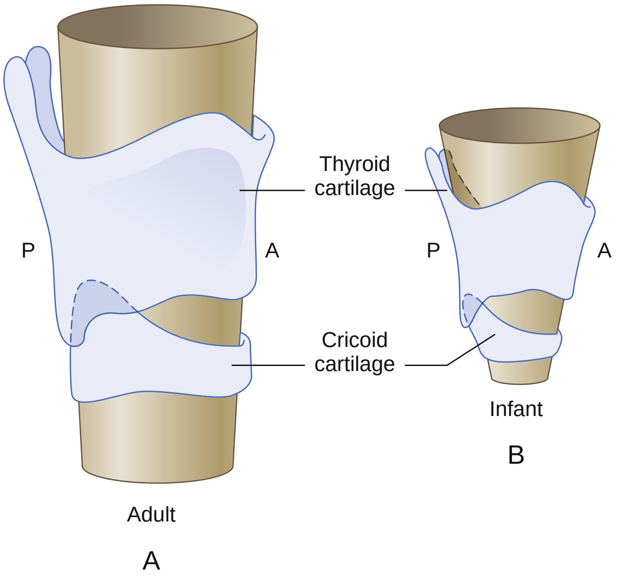

Fig. 77.3 The narrowest part of the adult larynx and the pediatric larynx is at the level of the cricoid cartilage. Traditionally, the adult larynx was thought to be cylindrically shaped, but autopsy data suggest that the narrowing in adults (A) is not as pronounced as it is in infants (B). The narrowest part of the infant larynx occurs at the level of the cricoid cartilage; the normal adult configuration of the larynx is not achieved until the teenage years. This anatomic difference is one of the reasons uncuffed tracheal tubes have been traditionally preferred for children younger than 6 years of age. *A,* Anterior; *P,* posterior. (From Coté CJ, Lerman J, Anderson BJ, eds. *A Practice of Anesthesia for Infants and Children.* 5th ed. Philadelphia: Saunders; 2013.)

metabolize medications rapidly increases for two reasons: (1) hepatic blood flow increases and hence more drug is delivered to the liver, and (2) the enzyme systems develop and are induced. The cytochrome P450 system is responsible for phase I drug metabolism of lipophilic compounds. This system reaches approximately 50% of adult levels at birth. The capacity for drug metabolism (e.g., caffeine) is reduced. However, this is not true for all lipophilic medications. The ability of neonates to metabolize some drugs is dependent on specific individual drug cytochromes. CYP3A (cytochrome P450, family 3, subfamily A) is generally present at adult values at birth, whereas other cytochromes are absent or reduced. Phase II reactions involve conjugation that makes the drug more water-soluble to facilitate renal excretion. These reactions are often impaired in neonates and result in jaundice (decreased bilirubin breakdown) and long drug (and their active metabolites) half-lives (e.g., the half-life of morphine and benzodiazepines is several days). Some of these reactions do not achieve adult activity until after 1 year of age.

A preterm infant's liver has minimal glycogen stores and is unable to manage large protein loads. These differences account for the neonate's tendency toward hypoglycemia and acidemia and for the failure to gain weight when the diet contains too much protein. Additionally, plasma levels of albumin and other proteins necessary for the binding of drugs are lower in full-term newborns (and are even lower in preterm infants) than in older infants (Fig. 77.5). This condition has clinical implications regarding neonatal coagulopathy (e.g., need for vitamin K at birth), as well as for drug binding and its pharmacodynamic effects; the lower the albumin value, the less protein binding of some drugs with resultant greater levels of unbound drug (i.e., unbound drug is the portion available to cross biologic membranes). In addition, the binding of some drugs to albumin may be altered in the presence of hyperbilirubinemia in the neonatal period; this effect is more important for drugs with high protein binding because a greater fraction of unbound drug will occur.

Gastrointestinal System

At birth, gastric pH is alkalotic; by the second day of life, pH is in the normal physiologic range for older children. The ability to coordinate swallowing with respiration does not

TABLE 77.3 Development of Glomerular Filtration Rate in the Term Newborn

Age	Glomerular Filtration Rate (mL/min/1.73 m^2 mean)	Range
1 day	24	3-38
2-8 days	38	17-60
10-22 days	50	32-68
37-95 days	58	30-86
1-2 years	115	95-135

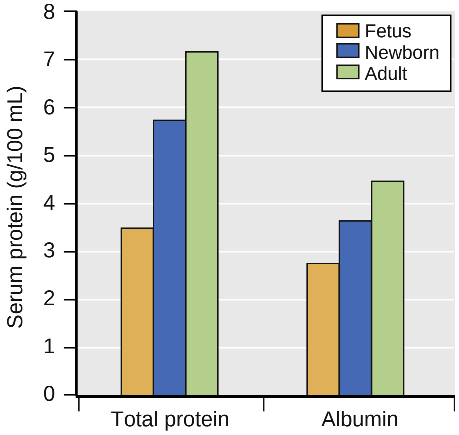

Fig. 77.5 Total serum protein and albumin values change with maturation. Total protein and albumin are less in preterm infants than in term infants and less in term infants than in adults. The result may be pharmacokinetic and pharmacodynamic alterations for drugs with a high degree of protein binding because less drug is protein bound and more is available for clinical effect. (From Ehrnebo M, Agurell S, Jalling B, et al. Age differences in drug binding by plasma proteins: studies on human foetuses, neonates and adults. *Eur J Clin Pharmacol.* 1971;3:189–193; Coté CJ, Lerman J, Anderson BJ, eds. *A Practice of Anesthesia for Infants and Children.* 5th ed. Philadelphia: Saunders; 2013.)

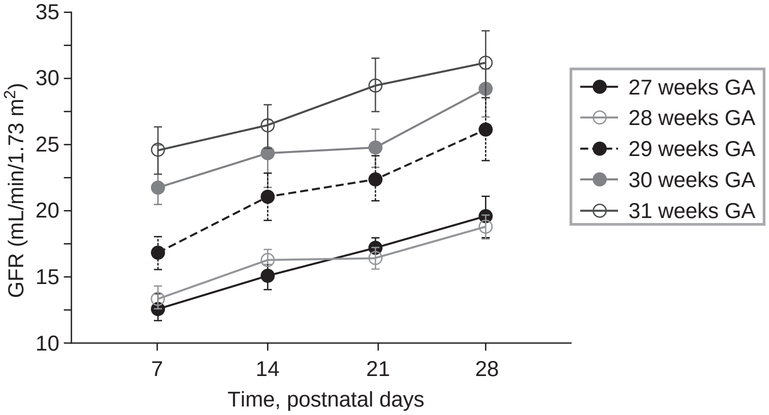

Fig. 77.4 Glomerular filtration rate *(GFR)* in the first month of life in preterm infants. The ability of the kidney to regulate large amounts of solutes and water is also limited during the first several months of life. These developmental changes have significant implications for drug excretion and fluid therapy, particularly during the first 4 weeks of life. Maturation of renal function may be delayed in sick and preterm neonates. Data are means ± SEM. (From Vieux R, Hascoet JM, Merdariu D, et al. Glomerular filtration rate reference values in very preterm infants. *Pediatrics.* 2010;125(5):e1186–e1192.)

fully mature until infants are 4 to 5 months of age, resulting in a high incidence of gastroesophageal reflux, particularly in preterm newborns. If a developmental problem exists within the gastrointestinal system, then symptoms will generally occur within 24 to 36 hours of life. Upper intestinal abnormalities are exhibited as vomiting and regurgitation, whereas lower intestinal abnormalities produce abdominal distention and a failure to pass meconium.

Hematology and Coagulation System

The fetus uses two compensatory mechanisms to assure adequate oxygen delivery in the relatively hypoxemic in utero environment. One of them is the increased red blood cell production resulting from increased fetal renal erythropoietin secretion in response to hypoxemia. The other compensatory mechanism is the production of fetal hemoglobin. Fetal hemoglobin has a high affinity for oxygen, causing a leftward shift in the oxyhemoglobin dissociation curve, increasing oxygen uptake at the lower oxygenated placental vascular bed. Hemoglobin levels are high at birth (160-240 g/L) but rapidly decrease during the first 3 months of life because of decreased renal erythropoietin production in the normoxic ex utero environment. Fetal hemoglobin will be progressively replaced by adult hemoglobin during the first 6 months of postnatal life. The extent of this physiologic anemia is more important in premature infants and may contribute to the need for perioperative blood transfusion.

The hemostatic system of the neonate and infant has many unique features compared to adults.[18-20] At birth, levels of vitamin K-dependent coagulation factors are low. They reach adult levels by 6 months of age. Fibrinogen levels are comparable between newborns and adults. However, fibrinogen polymerization does not reach its full capacity during the first few postnatal months, thereby leading to prolonged thrombin time. Platelet number at birth is also comparable to adults, but platelet function is impaired during early life. Despite these apparent deficits, the postnatal period represents a hypercoagulable state, since inhibitors of coagulation are also decreased by 30% to 50% in the newborn. Antithrombin III and protein S levels reach maturity by 3 months of age whereas protein C and plasminogen levels reach adult levels after 6 months of life. The overall results of this hypercoagulable state are higher risks of thrombotic complications in neonates and infants.[21] Children between 1 and 16 years of age have a 25% lower ability to form thrombin compared to adults, and the incidence of venous thrombosis in this population is estimated to be very low (0.05%-0.08%).[19,22] At adolescence, the physiology of the coagulation system matures. In the adolescent population, additional factors such as smoking, obesity, pregnancy, and use of oral contraceptives become relevant. As a result of some of these factors, recent guidelines recommend *considering* thromboprophylaxis in postpubertal adolescents.[23]

In utero, the immune system of the fetus remains tolerant to maternal alloantigens. After birth, exposure to myriads of environmental antigens, including those derived from intestinal bacteria, leads to a rapid development of the immune system.[24] However, full maturation of both the innate and adaptive immune systems is achieved after several years of life. Therefore young children are at increased risk from many pathogenic viruses, bacteria, fungi, and parasites when compared to adults.

Central Nervous System

In humans, the neural tube is formed between the third and fourth week of pregnancy and is followed by an active phase of cell proliferation and migration during the second trimester. With particular relevance to neonatal and pediatric perioperative care, the most intense phase of brain development takes place between the beginning of the third trimester of pregnancy and the first few years of postnatal life. During this period, also called the brain growth spurt, the nervous system undergoes important differentiation, including the formation of myriads of synaptic contacts between neurons. Neural activity plays a preponderant role in these events especially during critical periods of development when the nervous system is particularly sensitive to and relies on external stimuli to drive differentiation of neuronal networks. Pharmacologic interference with physiologic activity patterns during this period may lead to impaired brain development.

Both premature and term newborns show strong pain behavior that is more diffuse and untuned when compared to older children and adults. The first functional and reflex responses to tactile and noxious stimuli are aimed to protect the individual from tissue damage and can trigger a range of physiologic responses throughout the whole organism. The onset of pain awareness or “feelings” in humans remains undefined and largely debated. Nevertheless, there is evidence that early painful experiences, even if nonconscious, might alter subsequent central nervous system (CNS) function and that adequate pain relief can improve outcome.[25-27]

Thermoregulation

Infants are especially vulnerable to hypothermia because of the large ratio of body surface area to weight, the thinness of the skin, and a limited ability to cope with cold stress.[28] Cold stress causes increased oxygen consumption and a metabolic acidosis, particularly in preterm infants because of even thinner skin and limited fat stores. The infant compensates by shivering and nonshivering (cellular) thermogenesis (metabolism of brown fat); however, the minimal ability to shiver during the first 3 months of life makes cellular thermogenesis the principal method of heat production. As a result of these issues, managing heat loss is vital for newborns undergoing anesthesia and surgery. Placing the baby on a warming mattress and warming the surgical unit (80°F or warmer) will reduce heat lost by conduction. Keeping the infant in an incubator and covered with blankets minimizes heat lost through convection. The head should also be covered, since heat loss from the scalp is significant. Heat lost from radiation is decreased with the use of a double-shelled isolette during transport. Heat lost through evaporation is lessened by humidification of inspired gases, the use of plastic wrap to decrease water loss through the skin, and warming of skin disinfectant solutions. Hot air blankets are the most effective means of warming children; at the same time, especially in neonates, overheating must be avoided. Anesthetics also impact thermoregulation, particularly nonshivering thermogenesis in neonates.

Pharmacology

DEVELOPMENTAL PHARMACOLOGY

For nearly all drugs used in anesthesia, the dose required in children and adults differs. These differences are due to factors such as growth, maturation, and differing profiles of concurrent morbidity.[29] A thorough understanding of developmental pharmacology may reduce drug error in children.[30] Size alone cannot predict the differences between adults and children.[31] In adults, many drugs are given on a per kilogram basis. This assumes clearance and volume of distribution remain fixed relative to weight. This assumption is not valid for children. Pharmacokinetics in children varies with body composition, renal and hepatic function, and with altered protein binding. Renal and hepatic function in turn changes with age as relative blood flow and organ maturity change with age. The pharmacodynamics of anesthesia drugs may also differ substantially in children. The changes in pharmacokinetics and pharmacodynamics are most pronounced in neonates. It is important to note that for many drugs, knowledge is limited regarding drug pharmacology in children in general and infants and neonates in particular. The evidence upon which to guide practice is limited; as a result, many anesthesia drugs are used "off label" in small children.[32]

Body Composition

The body compartments (e.g., fat, muscle, water) change with age (Fig. 77.6).[33] Total body water content is significantly higher in preterm infants than in term infants and in term infants than in 2-year-olds. Neonates and infants have a substantially greater extracellular fluid volume compared to intracellular fluid volume. Fat and muscle content increases with age. These alterations in body composition have several clinical implications for neonates. First, a drug that is water soluble has a large volume of distribution and usually requires a large initial dose (mg/kg) to achieve the desired blood level (e.g., most antibiotics, succinylcholine). Second, because the neonate has less fat and muscle, a drug that depends on the redistribution into fat or muscle for the termination of its action will have a long clinical effect (e.g., fentanyl, propofol, and thiopental).

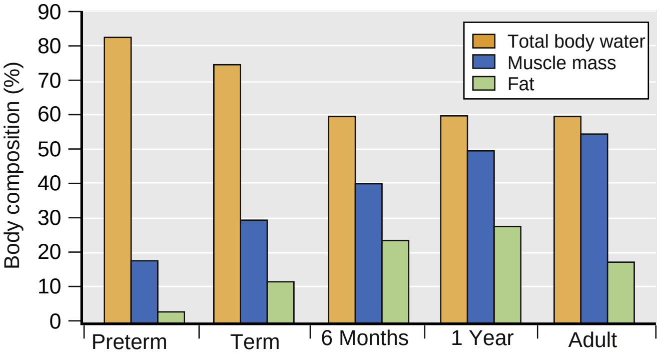

Fig. 77.6 Body composition rapidly changes in preterm and term infants during the first 12 months of life. Their high water content provides a large volume of distribution for water-soluble medications, whereas their low fat and muscle content provides a small reservoir for drugs that depend on redistribution into these tissues for the termination of the drug effect. Thus body composition may significantly affect pharmacokinetics and pharmacodynamics. (Data from Friis-Hansen B. Body composition during growth. In vivo measurements and biochemical data correlated to differential anatomical growth. *Pediatrics.* 1971;47:264; Coté CJ, Lerman J, Anderson BJ, eds. *A Practice of Anesthesia for Infants and Children.* 5th ed. Philadelphia: Saunders; 2013.)

Protein Binding

Neonates have reduced total plasma protein levels, including lower levels of albumin (which binds acidic drugs such as diazepam and barbiturates) and α_1 acid glycoprotein (which binds lidocaine and alfentanil). Reduced protein levels mean that drugs that are highly protein bound will have a higher free fraction and hence a greater drug effect; however it is important to note that this is only clinically relevant for drugs that have a very high degree of protein binding, a high extraction ratio, and a narrow therapeutic index (such as lidocaine). Some drugs, such as caffeine and ceftriaxone, may also displace bilirubin from plasma proteins increasing the risk of kernicterus in sick neonates.

Clearance

Clearance is the fundamental parameter in predicting drug elimination. It is also an important characteristic for determining duration of effect, dosing interval, and infusion rate. Drugs are cleared through a combination of metabolism and excretion. Clearance changes with age in a complex manner.[34] Clearance (expressed as L/h/kg) is greater in a toddler than it is for an older child. The difference is related to a nonlinear relationship between many aspects of organ function and size. This nonlinear relationship is not related to organ maturity and is surprisingly constant across different aspects of organ function, age, and species. It is known as *allometry* and can be expressed as

$$\text{Function} = (\text{scaling constant}) \times (\text{body mass})^{(\text{allometric exponent})}$$

Using body surface instead of body mass results in an allometric exponent of approximately 2/3 and is a reasonable predictor of clearance. Other pediatric pharmacologists argue that an allometric exponent of 3/4 better reflects actual function. Allometry alone, however, does not explain changes to clearance in the infant and neonate. For these infants, organ maturity has a substantial impact. A sigmoid hyperbolic or Hill model, in addition to allometry, is needed to predict clearance in this age group. Using postmenstrual age provides a better fit than chronologic age, consistent with organ maturity being on a continuum from fetal to postnatal life. The time to full maturation of renal and hepatic clearance varies between drugs. In general the slope is steepest in the neonatal period and full maturity is achieved by 2 years of age (Fig. 77.7).[29]

Many drugs such as succinylcholine, atracurium, and remifentanil undergo clearance independent of the liver or kidney. The nonspecific esterases that metabolize remifentanil are mature at birth.[35] The clearances for these drugs do not require an adjustment for maturation and can be predicted largely through allometry alone.

For drugs that require hepatic or renal clearance, neonates and infants will have a lower clearance resulting in longer elimination half-times, and hence infrequent dosing and lower infusion rates at steady state. In older children, elimination half-times may appear to be shorter, but this difference tends to disappear with allometric (body mass) scaling.

In addition to the differences in drug pharmacokinetics in neonates, other factors will have influence on drug dosing and clearance. Some of the critical factors include sepsis, congestive heart failure, and increases in intraabdominal pressure affecting renal and hepatic function.

Pharmacodynamic Differences

In older children pharmacodynamic properties of most anesthetic agents are probably similar to those in adults, albeit with some notable exceptions such as anticoagulants.[20,36] In infants and neonates much less is known about the pharmacodynamics of anesthetic agents. The lack of data are partly due to the lack of robust and validated measures of various aspects of anesthetic effect in the infant and neonatal population. For example, fundamental anesthesia endpoints such as pain, memory, and even unconsciousness can be difficult to assess in infants. Surrogate measures of anesthesia effect, such as the EEG, are also unreliable in infants. With increasing understanding of the developmental neurobiology of pain and consciousness it is likely that we will identify other clinically significant pharmacodynamic differences in infants.

INHALED ANESTHETICS

Potency of Inhaled Anesthetics in Children

The expired minimum alveolar concentration (MAC) of an inhaled anesthetic required in children changes with age (Fig. 77.8).[37-44] Anesthetic requirement is smaller for preterm than for term neonates and smaller for term neonates than for 3-month olds. Infants have a higher MAC than that of older children or adults; the reasons for these age-related differences in MAC are not known. When considering the impact of age on MAC, it must be noted that the evidence is limited; the number of studies and the number of children in each study are small.

It is also important to note that MAC measures only one aspect of anesthesia effect and reflects primarily a spinal cord reflex. Compared to adults, older children have a similar relationship between MAC and other measures of anesthetic effect. The ratio of MAC to $\text{MAC}_{\text{awake}}$, $\text{MAC}_{\text{intubation}}$, $\text{MAC}_{\text{LMA insertion}}$, $\text{MAC}_{\text{extubation}}$, and MAC_{BAR} are similar in children to adults.[45-48] The relationship between MAC and the EEG, and hence most anesthesia depth monitors, is not as consistent in children and adults. Children have a higher BIS (bispectral index) for a specific fraction of MAC.[49,50] The significance of this is unclear. In infants and neonates there are no data to determine how MAC relates to other aspects of anesthetic effect. It is clear that the relationship between MAC and the EEG is substantially different in infants compared to adults, but once again the clinical significance of this is unclear.

Halothane, sevoflurane, isoflurane, and desflurane all produce a dose-dependent reduction in systemic blood

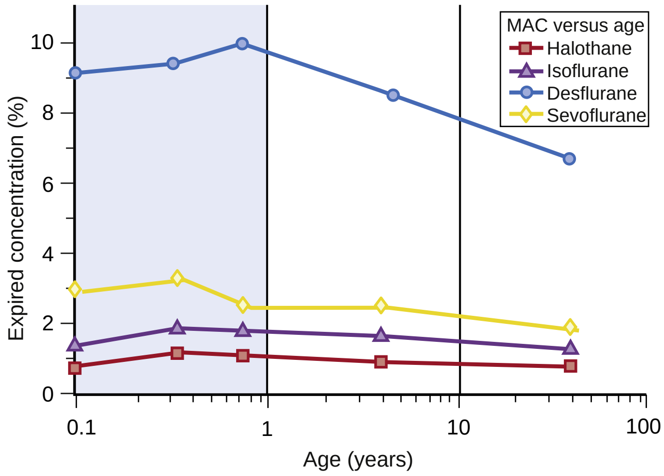

Fig. 77.8 The minimum alveolar concentrations *(MACs)* of four commonly used inhaled anesthetics are plotted versus age. (From references 37–44.)

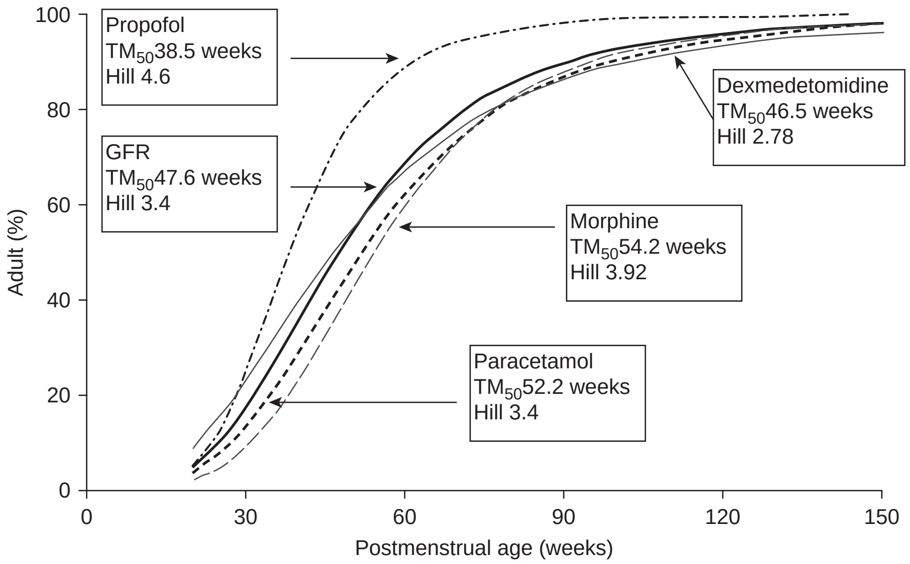

Fig. 77.7 Clearance maturation, expressed as a percentage of mature clearance, of drugs in which glucuronide conjugation plays a major role. *GFR,* Glomerular filtration rate. (From Sumpter A, Anderson BJ. Pediatric pharmacology in the first year of life. *Curr Opin Anaesthesiol.* 2009;22:469–475.)

pressure. It is unclear if this is a direct effect on myocardial contractility and vascular smooth muscle or an indirect effect via autonomic or neurohumoral reflexes. The myocardial depressant effect is greater in neonates compared to older children.[51] All of these agents also have a dose-dependent effect on ventilator drive and response to carbon dioxide.[52-54]

Pharmacokinetics of Inhaled Anesthetics in Children

The rate of rise of inhalational anesthetic concentration depends on rate of delivery determined by the inspired concentration, minute ventilation, and ratio of minute ventilation to residual functional capacity; it also depends on the rate of uptake that is determined by the cardiac output, tissue/blood solubility, and alveolar to venous partial pressure gradient.

Attainment of steady state, where the alveolar and inspired fractions equilibrate, is faster in children than adults. This difference is due to a greater minute ventilation relative to functional residual capacity as well as a lower tissue/blood solubility. This effect in children is greater for more soluble agents such as halothane and less for sevoflurane and desflurane.

The faster attainment of steady state in neonates can increase the risk of overdose during induction of anesthesia, particularly if a high inspired concentration is used for an excessively long period. The risk may be greater for agents when greater MAC multiples can be delivered by the vaporizer; for example, a halothane vaporizer can deliver up to 5.75 MAC multiples versus 2.42 MAC multiples for a sevoflurane vaporizer (Table 77.4).

TABLE 77.4 Minimum Alveolar Concentration Multiples for a Neonate Allowed by Current Vaporizers

Agent	Maximum Vaporizer Output (%)	MAC (%)	Maximum Possible MAC Multiples
Halothane	5	0.87	5.75
Isoflurane	5	1.20	4.2
Sevoflurane	8	3.3	2.42
Desflurane	18	9.16	1.96

MAC, Minimum alveolar concentration.

Halothane

Halothane is now rarely, if ever, used in the United States and many other countries; however, it is still widely used in developing countries. Halothane is a relatively potent agent, but has a greater blood solubility and slower induction and emergence if similar MAC multiples of inspired concentrations are used. It does not have a noxious smell and hence, prior to the use of sevoflurane, was the agent of choice for inhalational inductions in children. Halothane, being a polyhalogenated alkane, has subtle differences in pharmacodynamic properties compared to the other ether inhalational anesthetics. Halothane has more "analgesic" properties than the ethers and has a higher BIS at equivalent MAC multiples. The MAC of halothane is low in neonates, highest in infants, and then steadily declines with age.

Halothane is a potent myocardial depressant that can have profound effects on neonates and children. Halothane also causes sensitization of the myocardium to arrhythmias. The first Pediatric Perioperative Cardiac Arrest (POCA) registry study reported that halothane was a major cause for perioperative cardiac arrest. It was thought to be particularly dangerous with the use of controlled ventilation without reducing the inspired concentration after induction.[55] The decline in cardiac events in subsequent POCA audits has been attributed to the decline in use of halothane in the United States.[56] At the same time, halothane may be used safely, but care should be exercised particularly if the anesthesiologist is not experienced with its use.

Sevoflurane

Sevoflurane is a polyhalogenated ether. It has a low blood solubility facilitating a relatively rapid inhalational induction. Sevoflurane is less pungent than isoflurane and desflurane and has become the agent of choice for inhaled induction of anesthesia in children. Unlike other inhalational agents, the MAC is similar with neonates and infants, but like other agents becomes lower with age after infancy: 3.3% for neonates, 3.2% for infants 1 to 6 months old, and 2.5% for children older than 6 months.[37,38] Sevoflurane is associated with a greater incidence of emergence delirium compared to halothane (see later). Sevoflurane is also reported to cause epileptiform changes in the EEG when delivered at high concentrations in children. The clinical significance of these EEG changes is not clear.[57]

Isoflurane

Isoflurane, a polyhalogenated ether, has a blood solubility between halothane and sevoflurane. As with sevoflurane, it has a relatively lower MAC in neonates, peaks in infancy, and then declines with age. It is more potent than sevoflurane but has a relatively more noxious smell, which makes an inhalational induction with it unacceptable for most children.

Desflurane

Desflurane is another polyhalogenated ether, with a blood solubility lower than isoflurane or sevoflurane. Similar to sevoflurane and isoflurane, desflurane's MAC peaks in infancy, is lower in neonates, and declines with age after infancy.[40,58] The low solubility facilitates a more rapid emergence. It is however not suitable for inhalational induction in children because of its pungent odor and an unacceptable incidence of laryngospasm (~50%).[59] It is however suitable for maintenance of anesthesia in children although the package insert indicates that it is not recommended for maintenance in children without tracheal tubes.

Nitrous Oxide

Nitrous oxide is an odorless gas that has a low solubility in blood, but is relatively nonpotent. The MAC of nitrous oxide has not been accurately determined in children. When nitrous oxide is used with an inhaled anesthetic, it reduces the concentration required for the more potent inhalational agents. It may speed the uptake of more potent anesthetics, but the underlying theory behind this "second gas" effect has been challenged. This characteristic is probably of limited clinical relevance. Nitrous oxide is a weak analgesic; it can be used alone or in conjunction with other agents for procedural sedation and analgesia for children.[60-62] Since it is odorless, it is also commonly used for an inhalational induction in cooperative children. For example, breathing high concentrations for a short period can provide considerable sedation prior to adding sevoflurane. In many institutions the routine use of nitrous oxide during maintenance of anesthesia has declined since it is associated with an increased risk of postoperative nausea and vomiting in adults; however studies have shown little evidence that nitrous oxide has any impact on postoperative nausea and vomiting in children.[63,64]

Xenon

Xenon is another odorless anesthetic gas that has a relatively low potency. While it is currently not routinely used, it has some potential advantages over other anesthetic agents. The MAC in children is unknown. In adults it has remarkably little cardiovascular effect. It has thus been proposed as a potentially superior anesthetic for children with significant congenital heart disease but only preliminary studies have evaluated this to date.[65,66] Its high cost mandates the use of either very low fresh gas flows or complex scavenging and recycling systems. This may reduce the practicality of its use in many pediatric settings.

Emergence Agitation and Delirium

Children can become agitated on emergence or shortly after arrival in the postanesthesia care unit (PACU). The reported incidence of agitation varies enormously, reflecting the variety of definitions of agitation and delirium used in various studies. The potential list of causes or associated factors is long. Agitation may be due to many factors including pain, cold, full bladder, presence of restrictive casts, fear, anxiety due to parental separation, or simply having a "tantrum." Agitation is best measured with the Cravero scale.[67] The initial management of agitation is to try to identify or rule out likely causes. In some cases agitation may be due to delirium. Delirium is characterized by reduced awareness of the environment and altered cognition or perceptual disturbances. Typically the child is disoriented and does not respond to parents or staff. There is generally no eye contact and the child cannot be consoled.[68] If the delirium is associated with thrashing around or violent movement, this is known as "emergence delirium." Emergence delirium occurs most frequently in preschool children. It is distressing to staff and parents. It may also lead to self injury, and dislodging dressings, drains, and intravenous lines. In most cases, emergence delirium may persist for 10 to 20 minutes but is self-limiting. Delirium may also be hypoactive; in this situation, the child has a delirium, but is inactive and not agitated, and thus is at less risk of doing harm to themselves.

The cause for delirium is not precisely known. It may relate to the mode of awakening.[69] It is intriguingly similar to night terrors in children. It is more common when maintenance anesthesia included either sevoflurane or desflurane. It is unusual after total intravenous anesthesia (TIVA) with propofol. Many agents have been found to reduce the incidence.[70-72] The most effective is using TIVA or giving 2 to 3 mg/kg of propofol before emergence.[73] Fentanyl and α_2 agonists have also been found to be effective.[74] Propofol, clonidine, and midazolam have all been described as useful in management. When managing delirium other causes for agitation should be considered, particularly pain. Emergence delirium may occur after painless procedures; however there is also some evidence that pain may increase the risk of emergence delirium. Other physiologic changes, including hypoxia, metabolic derangement, and hyponatremia, may also cause agitation or delirium, so must be ruled out, particularly if the delirium is prolonged.

INTRAVENOUS GENERAL ANESTHETICS

Propofol

The pharmacokinetics of propofol have been well described in children. In children the volume of distribution is greater than in adults and there is a more rapid redistribution. Clearance is similar in children to adults; however clearance is longer in preterm neonates. The dose for induction increases with decreasing age. The median effective dose (ED_{50}) for loss of eyelash reflex is 3 mg/kg in infants aged 1 to 6 months, and 1.3 to 1.6 mg/kg in children aged 1 to 12 years. The pharmacokinetics of propofol in neonates has not been as well described; however, the induction dose is generally less than for older infants. Use of propofol has been associated with profound hypotension in neonates.[75] A potential drawback is pain on injection. Numerous strategies have been described to reduce this pain. The most effective is probably using a large vein, or adding lidocaine (0.5-1.0 mg/kg) to the propofol, or injecting lidocaine before the propofol. Propofol is not contraindicated in children with egg allergy.[76]

A major concern with propofol is the potential for propofol infusion syndrome (lipemia, metabolic acidosis, rhabdomyolysis, and hyperkalemia followed by refractory cardiovascular collapse), which is generally associated with high-dose infusions for an extended period (usually days in an intensive care unit [ICU] environment).[77] The onset may be subtle and unnoticed followed by rapid demise. The mechanism underlying propofol infusion syndrome remains unclear. It may be related to mitochondrial lipid metabolism.[78]

Total Intravenous Anesthesia in Children

TIVA is becoming increasingly popular in pediatric anesthesia.[79-81] Propofol and remifentanil are the main agents used. In children TIVA has been suggested to have many advantages including reduced emergence agitation and emergence delirium, faster recovery, reduced postoperative vomiting, and fewer airway complications on emergence. These advantages are all plausible; however there are few well-designed studies to test these assertions. One limitation of TIVA in children is the need for specific and well-validated pediatric algorithms. Adult target-controlled infusion models are not best suited for children.[82] The Paedfusor model is one pediatric-specific algorithm that is widely used for children.

Thiopental

In most countries, propofol has largely replaced thiopental in pediatric anesthesia. The ED_{50} of thiopental is 3.4 mg/kg in neonates, 6 mg/kg in infants, 4 mg/kg in preschool children, 4.5 mg/kg in children aged 4 to 7 years, 4.3 mg/kg in children aged 7 to 12 years, and 4.1 mg/kg in older children. Clearance is slower in neonates. Limiting the total dose to 10 mg/kg or less in older children minimizes the possibility of prolongation of anesthesia caused by residual barbiturate sedation.

Ketamine

Ketamine has a similar volume of distribution in children compared to adults, but the clearance is reduced in infants. Ketamine has a number of niche uses in pediatric anesthesia. Ketamine may be used for induction of anesthesia (1-3 mg/kg intravenously and 5-10 mg/kg intramuscularly). The intramuscular route is well described for larger uncooperative children where intravenous and inhalational induction are impossible and other forms of premedication are refused. The intramuscular dose may have a benzodiazepine added to reduce the risk of hallucinations and an anticholinergic agent to reduce the risk of hypersecretion. For relatively brief procedures a large intramuscular dose may lead to significantly delayed emergence.

Compared to equipotent doses of other intravenous anesthetics, ketamine causes relatively little cardiovascular or respiratory depression and is less likely to result in airway obstruction. It is thus favored as a safer drug in resource poor settings. However, although spontaneous respirations and a patent airway are usually maintained, apnea and laryngospasm may still occur. It is also frequently used in the pediatric emergency department for brief painful procedures. Ketamine may be used alone or in combination with other agents as an effective premedication. Given its cardiovascular stability it may be the optimal premedication for children with significant cardiovascular disease such as children with congenital heart disease. Ketamine is increasingly used as a postoperative analgesic, either alone or in combination with other agents.

Etomidate

Clearance is similar in children to adults; however the volume of distribution is larger in children and hence a larger initial bolus is required. Concerns regarding anaphylactoid reactions and suppression of adrenal function have limited widespread use of this anesthetic in children. As with propofol, the incidence of pain on intravenous administration is frequent. Etomidate has minimal cardiovascular suppression and thus it is useful in children who are critically ill and those with a head injury. Etomidate has gained increasing popularity for airway management in the emergency department.

α_2 AGONISTS

α_2 Agonists are increasingly used in pediatric anesthesia. Uses include sedation, premedication, analgesia, prevention of emergence delirium, and as an adjunct to extend the duration of action of regional nerve blockade. α_2 Agonists cause a dose-dependent reduction in heart rate and blood pressure; however this is rarely clinically relevant in the doses commonly described.

Clonidine

Clonidine is increasingly used for premedication. To be optimally effective 4 mcg/kg clonidine should be given orally 45 to 60 minutes prior to induction. There is some evidence that clonidine is superior to midazolam as a premedicant in terms of sedation, postoperative agitation, and postoperative pain.[83] Similar to many other drugs, the clearance of clonidine is reduced in neonates; however it rises to 82% of adult levels by 1 year of age.[84]

Dexmedetomidine

Dexmedetomidine has greater selectivity for the α_2 adrenoreceptor than clonidine, and hence produces less hypotension and bradycardia compared to clonidine. It also has minimal respiratory depressive effects. The sedation provided by dexmedetomidine is similar to natural sleep. Thus with stimuli, children may be more easily aroused from dexmedetomidine sedation compared to other sedative agents. Dexmedetomidine has been widely used as a sedative in the intensive care setting. It has also been used as a sole sedative for medical imaging in children. The loading dose of 1 to 2 μg/kg is typically given over 10 minutes followed by an infusion of 0.5 to 1 μg/kg/h.[85] This may however produce a more prolonged recovery compared to other regimens. Dexmedetomidine has also been used for cardiac catheterization, awake-craniotomies, and to facilitate opioid withdrawal. Dexmedetomidine may produce a biphasic hemodynamic response with a bolus producing an initial increase in blood pressure before a mild reduction in blood pressure. The clearance is reduced in neonates.[86]

Dexmedetomidine is increasingly used intranasally for premedication where it has a bioavailability of 80%. A dose of 1 to 2 μg/kg is usually used for intranasal premedication, taking 30 to 40 minutes for peak effect. Several studies have found intranasal dexmedetomidine to be superior to midazolam for premedication in children.[87,88]

OPIOIDS

Morphine

Morphine is frequently used for postoperative analgesia. In children, as in adults, there is also a large variability in pharmacodynamic and pharmacokinetic profile and thus doses should be titrated to effect. Morphine is metabolized by both glucuronidation and sulfation. In adults sulfation is a minor pathway; however in neonates it is relatively more dominant. The clinical significance of this is unclear. Clearance is low in neonates but reaches adult levels at 6 to 12 months of age. The most worrisome adverse effect of morphine is respiratory depression. In animal models neonates are more susceptible to respiratory depression compared to older animals, perhaps due to an immature blood-brain barrier. There is some evidence that human neonates are also more susceptible to the respiratory depressive effects of morphine; however the mechanism remains unclear. Nevertheless it should be used cautiously in infants, especially preterm infants.

Codeine

Codeine is a morphine-like opioid with approximately 10% the potency of morphine. It has rapid oral absorption and 90% bioavailability. These features resulted in it previously being used extensively as an oral analgesic (1 mg/kg). Approximately 10% of codeine is metabolized to morphine and thus a considerable amount of its analgesic action is through this mechanism of metabolism. There is considerable variation in this metabolism with poor, rapid, and ultra-rapid metabolizers. About 10% of Caucasians and 30% of Hong Kong Chinese are poor metabolizers in whom codeine provides only poor analgesia.[89] In contrast, 1% of some Caucasian groups and 30% of Ethiopians are ultra-rapid metabolizers. Ultra-rapid metabolizers are at risk of increased clinical response including profound respiratory depression that has been associated with death in children.[90] For this reason, codeine is increasingly being used infrequently. The U.S. Food and Drug Administration (FDA) issued a "black box" warning against its use in children after tonsillectomy.

Meperidine

The use of meperidine is declining because of concerns over the accumulation of the metabolite normeperidine with multiple doses, which may cause seizures. Meperidine has a potency of approximately one tenth that of morphine and a shorter time to peak effect. The elimination of meperidine is reduced in neonates.

Fentanyl

Fentanyl is commonly used in pediatric anesthesia for intraoperative analgesia. It has greater hemodynamic stability than morphine. High doses of 10 µg/kg or greater can be used to maintain cardiovascular stability. The clearance is markedly reduced in preterm infants but rises to 80% of adult values by term. Adult levels of clearance are achieved within the first few weeks post term. The volume of distribution is greatest in neonates (5.9 L/kg) and steadily declines with age to 1.6 L/kg in adults.

Alfentanil

The clearance of alfentanil in preterm neonates is markedly reduced and the volume of distribution is greater than older infants. Pharmacokinetic data are generally sparse and somewhat contradictory but volume of distribution and elimination half-life are similar between infants aged 3 to 12 months and older children.[91]

Sufentanil

Sufentanil is used mainly for pediatric cardiac surgery. Like other similar agents, in neonates sufentanil has a greater volume of distribution, reduced clearance, and longer elimination half-life.

Remifentanil

The main advantage of remifentanil is its extremely brief half-life. The elimination half-life is 3 to 6 minutes and is independent of dose and duration. Remifentanil is degraded by nonspecific plasma and tissue esterases and metabolism is not affected by butyrylcholinesterase deficiency. The importance of maturation of renal and hepatic function is minimal and the drug has great utility in infants with hepatic or renal failure. The differences in remifentanil's half-life among neonates, infants, and adults are minimal.

One study examined its pharmacokinetic effects in children and found age-related differences in the volume of distribution and clearance but not in half-life with volume of distribution being greater in infants compared to older children (Fig. 77.9).[92] Contrary to the pharmacokinetics of most drugs, neonates are able to clear the drug more rapidly than older children. Of further interest is the very small patient-to-patient variability in pharmacokinetic parameters when compared with similar studies examining other opioids, particularly in infants and neonates. The particularly favorable pharmacokinetics in neonates allows the provision of a deep opioid-induced plane of anesthesia while avoiding cardiovascular depression and the need for postoperative ventilation.

An initial dose of remifentanil may be required prior to infusion; however, a rapid large bolus may produce hypotension and bradycardia. A combination of 3 µg/kg remifentanil with 3 to 4 mg/kg propofol is an alternative to succinylcholine to facilitate endotracheal intubation.[93,94] An acute tolerance similar to that occurring in adults has also been described in children. If postoperative pain is anticipated, adequate long-acting analgesia should be given well before the remifentanil infusion is discontinued.

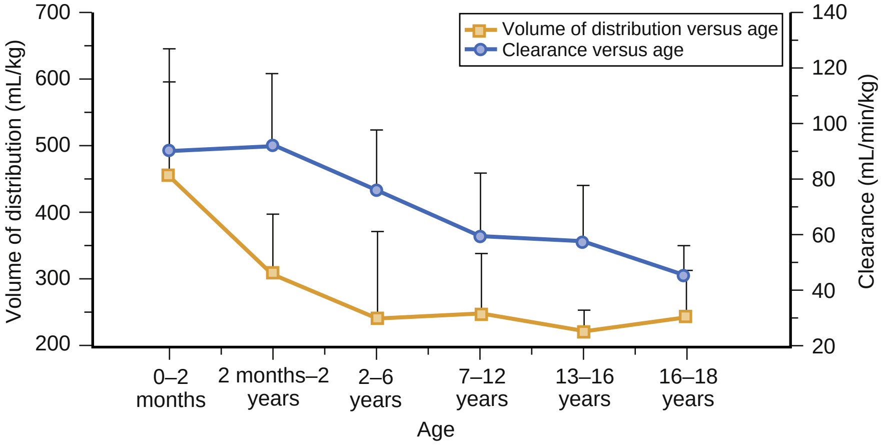

Fig. 77.9 Remifentanil is the newest potent opioid available for the care of neonates. Unlike virtually all other medications, its clearance is more rapid in neonates than it is in older children, probably because of elimination of remifentanil by nonspecific plasma and tissue esterases, as well as the larger volume of distribution in neonates. The importance of this observation is that developmental immaturity of liver and renal function does not affect the pharmacokinetics of remifentanil. (Data abstracted from Ross AK, Davis PJ, del Dear G, et al. Pharmacokinetics of remifentanil in anesthetized pediatric patients undergoing elective surgery or diagnostic procedures. *Anesth Analg.* 2001;93:1393–1401.)

Tramadol

Tramadol is a relatively weak opioid with less respiratory depressant effects. Two enantiomers provide analgesia; one is an opioid mu receptor agonist and the other inhibits uptake of serotonin and noradrenaline. Clearance is less in premature neonates but in children is similar to adults if standard allometric scaling is applied. Tramadol is metabolized by various pathways including via CYP2D6 to 0-desmethyltramadol. This metabolite has mu-receptor affinity approximately 200 times greater than tramadol.[95] The genetic polymorphism of CYP2D6 produces fast and slow metabolizers that may produce a variable response among children. The FDA has warned against using tramadol after tonsillectomy in children with obstructive sleep apnea. One oral formulation of tramadol for children has a concentration of 100 mg/mL and is administered in drops. This may increase the risk of errors in administration if milliliters are mistakenly given rather than drops, resulting in a potentially 10-fold overdose. This formulation has been replaced in some countries by an elixir of 10 mg/mL.

MUSCLE RELAXANTS AND REVERSAL AGENTS

Succinylcholine

Succinylcholine is highly water soluble and rapidly redistributes into the extracellular fluid volume. For this reason, the dose required for intravenous administration of this depolarizing muscle relaxant in infants (2.0 mg/kg) is approximately twice that for older children (1.0 mg/kg). Succinylcholine is also effective when given intramuscularly; reliable muscle relaxation occurs within 3 to 4 minutes after 5 mg/kg in infants and 4 mg/kg in children older than 6 months. The skeletal muscle relaxation produced by intramuscular administration may last up to 20 minutes. In an emergency situation, succinylcholine may be administered intralingually (via a submental approach), which will further speed the onset of relaxation because the drug is more rapidly absorbed from the tongue than from peripheral skeletal muscle.

Cardiac arrhythmias may follow intravenous administration. Prior intravenous administration of atropine (but not intramuscular administration of atropine as a premedication) reduces the incidence of arrhythmias. Cardiac sinus arrest may follow the first dose of succinylcholine but is more common after repeated bolus administrations; such arrest may occur in children of any age. Therefore a vagolytic drug should probably be intravenously administered just before the first dose of succinylcholine in all children, including teenagers, unless a contraindication to tachycardia (e.g., a cardiomyopathy) exists.

Succinylcholine has received significant attention because of the severity of its possible complications. The potential for rhabdomyolysis and hyperkalemia (particularly in boys younger than 8 years of age who have unrecognized muscular dystrophy), as well as the risk for malignant hyperthermia, suggests that succinylcholine should not be *routinely* used in children.[96] Increased jaw muscle tone (masseter spasm) after succinylcholine has been observed, particularly when halothane is used. Masseter tetany ("jaws of steel"), which prevents any mouth opening, is an extreme variation in increased masseter muscle tone. Such tetany may be an early sign of malignant hyperthermia, but certainly not all cases of tetany progress to malignant hyperthermia.

Succinylcholine is still used for emergency airway management including the management of severe laryngospasm and as part of a rapid sequence induction (RSI) where the child has a full stomach. High-dose nondepolarizing neuromuscular blockers such as rocuronium or a large dose of propofol and remifentanil have been proposed as alternatives to succinylcholine for RSI. Large-dose rocuronium produces adequate intubating conditions almost as quickly as succinylcholine in adults.[97] The advent of sugammadex has enabled the rapid reversal of large-dose rocuronium if needed. High-dose propofol and remifentanil may also produce timely adequate intubating conditions; however significant hypotension may occur.

Nondepolarizing Muscle Relaxants

A comparison of infants with older children and adults regarding responses to nondepolarizing muscle relaxants shows that infants are generally more sensitive to these drugs and that their responses vary to a greater degree. Although the initial dose per kilogram needed for neuromuscular blockade is often similar for children of all ages, the greater volume of distribution and reduced renal or hepatic function of neonates result in a slower rate of excretion and a prolongation of effect. Neuromuscular blockade occurs at a lower blood concentration in infants.

The choice of nondepolarizing muscle relaxant depends on the side effects and the duration of the desired muscle relaxation. If tachycardia is desired (e.g., with fentanyl anesthesia), then pancuronium may be an appropriate choice. Vecuronium, atracurium, rocuronium, and cisatracurium are useful for shorter procedures in infants and children; they may also be administered as a constant infusion. The method of excretion of atracurium and cisatracurium (Hofmann elimination and ester hydrolysis) makes these relaxants particularly useful in newborns and children with immature or abnormal hepatic or renal function. Vecuronium is valuable because no histamine is released; however, its duration of action is prolonged in newborns.

Rocuronium has a clinical profile similar to that of vecuronium, cisatracurium, and atracurium. Rocuronium can be administered intramuscularly. One study observed that acceptable conditions for intubation are produced by rocuronium within 3 to 4 minutes after 1 mg/kg intramuscularly in infants and 1.8 mg/kg intramuscularly in children older than 1 year of age; these effects were more dependable with deltoid than with quadriceps muscle injection.[98] Table 77.5 provides commonly recommended guidelines for doses. Routine pharmacologic antagonism of neuromuscular blockade is recommended in all children, even if they have clinically recovered. Recovery times vary between subjects and residual blockade may be difficult to detect, and may be associated with increased postoperative complications.

Sugammadex

Sugammadex is a cyclodextrin that rapidly encapsulates rocuronium, and to a lesser extent, vecuronium, forming a stable complex that prevents any further action of the muscle relaxant. The complex is excreted by the kidney. There are few data in children; however one study found that 2

TABLE 77.5 Commonly Used Muscle Relaxants and Reversal Agents in Pediatrics

Drug	Average Intubation Dose (mg/kg)	Category	Approximate Duration (minutes)
MUSCLE RELAXANTS*			
Pancuronium	0.1	Long acting	~45-60
Cisatracurium	0.1	Intermediate acting	~30
Vecuronium	0.1	Intermediate acting	~30
Rocuronium		Dose related:	
	0.3	Short acting	~15-20
	0.6	Intermediate acting	~30-45
	1.2	Long acting	~45-75
REVERSAL AGENTS†			
Edrophonium	0.3-1.0 mg/kg + atropine, 0.02 mg/kg		
Neostigmine	0.02-0.06 mg/kg + atropine, 0.02 mg/kg		

*The response of preterm and term neonates (who may be more sensitive to the drugs) to muscle relaxants varies greatly from patient to patient. Therefore all doses should be titrated to response. The recommended tracheal intubation doses may be reduced 30% to 50% in the presence of a potent inhaled agent.

†The dose of the reversal agent given to antagonize nondepolarizing neuromuscular blockade should be determined by the degree of residual neuromuscular blockade (i.e., the dose should be titrated to clinical effect).

mg/kg reversed moderate rocuronium-induced block in children and adolescents in a time that was similar to that seen in adults.[99,100]

THE IMPACT OF ANESTHESIA ON THE DEVELOPING BRAIN

Recently the FDA issued a warning that many general anesthetics may have a harmful effect on the developing brain.[101,102] The warning emphasizes that the risk is greater with prolonged and repeated anesthetics in children under the age of 3 years. This warning is based on a large amount of animal data and a more limited amount of human data. It has received some criticism.

Animal data

There is substantial preclinical evidence that many general anesthetics have the capacity to cause morphological and functional changes to the developing brain.[103-105] These changes have been demonstrated in a wide variety of species, ranging from the nematode to the nonhuman primate.[106,107] A variety of different morphological changes have been seen. Accelerated neuronal apoptosis is the most widely recognized.[108] Changes to dendritic morphology have also been described.[109] Apoptosis has also been described in glial cells.[110] Several mechanisms have been identified, and mitochondrial dysfunction may be important.[103] The effects are greatest with larger doses and longer exposure; however, it is difficult to identify the upper limit of duration of exposure that has no effect.[104] The effect also varies with age at the time of exposure. Generally the effects are greater in the more immature brain—which may translate to the late trimester of pregnancy or early infancy in humans, but some effects are also seen in older animals. The area of the brain affected may also vary with age of exposure. Effects are greatest with γ-aminobutyric acid agonists and N-methyl-D-aspartate antagonists and have been seen with propofol, benzodiazepines, volatile anesthetics, and ketamine. There is contradictory evidence for an effect with α_2 agonists. Functional experiments have demonstrated that animals, including nonhuman primates exposed to anesthesia in early life, may have deficits in learning and altered behavior; however not all experiments have demonstrated functional deficits and it is unclear if the functional deficits are a function of the observed morphologic changes.

Translating the Animal Data to Humans

There are considerable problems translating animal data to humans in general, and more challenging when considering age.[111,112] Translating dose ranges is problematic as is understanding exactly how a particular age of animal correlates to the age of a human. In small animals, homeostasis may be deranged during anesthesia and few models examine the impact of concurrent surgery. Human brains are complex and develop over a longer period. The impact of an injury in humans will depend on the type of injury and timing of the injury. Human brains can be extraordinarily vulnerable to injuries of a specific type at particular times, or demonstrate considerable plasticity and recovery. Importantly, genetic and environmental factors have a huge impact on resilience and recovery or vulnerability.

Human Study Outcomes

The human studies can be broadly grouped according to their design and the outcomes at which they look.[113] So far there is only one prospective trial with published results. All other studies are observational. This is a crucial point that will be explained later. Various study designs have been used.

The ***design*** of observational studies broadly consist of:

- *Data linkage population-based studies.* These studies use existing datasets that can be linked. They are inherently retrospective and limited by the outcomes and exposure variables that have already been collected. They can however be very large, examining whole country or whole state populations. The outcomes commonly used are some form of preschool test for school readiness, or school grades.

- *Use of existing birth cohorts or longitudinal studies.* These studies use existing data in longitudinal cohorts that have usually been set up for other purposes. They often include access to more detailed outcome measures including some psychometric outcomes; they may also include diagnoses of disability and school grades. While often large, they are not as big as the population linkage studies. The details of exposure may be limited but there are usually good data about other factors that may contribute to outcome.
- *Purpose built cohort studies.* These studies recruit children that have been exposed to anesthesia and match them to those that have not, and then test the children for a range of psychometric outcomes. These studies enable researchers to focus on neurodevelopmental areas of greatest interest but logistically it is difficult to recruit large numbers of children. Children may be recruited in various ways including from existing longitudinal studies.

Various **outcome measures** have also been used.[114]

- *School grades or school readiness tests.* These are of great interest and importance to families but they are coarse measures of neurodevelopment. A deficit may however exist in one aspect of neurodevelopment that is not reflected in school grades; conversely many other factors influence school grades, diluting any possible “injury” effect. Their advantage is not only their importance to families, but also that they are easy to obtain in very large numbers.
- *Diagnosis of a learning disorder or specific neurodevelopmental disorder.* These are also of great importance to the families and the community. A major problem is that the diagnosis may not always be clear and definitions of disorders vary between jurisdictions and over time. Another potential disadvantage is that these disorders are not common enough to be able to produce precise results except in very large studies.
- *Psychometric testing.* Many tests are available to test a wide range of neurodevelopmental domains. Apical tests, such as intelligence quotient (IQ), are composite scores that pool results from several domains. Apical tests have the best value as far as predicting future function, but using apical tests may miss deficits in some subdomains. Looking at multiple domains raises the problem of type 1 error (finding a “significant” association due to multiple testing). The psychology literature abounds with studies that are not replicable—partly because of this issue. If a “deficit” is found in only one or two of many subdomains tested then the results must be interpreted very cautiously until they are replicated in following studies. Performing psychometric testing is labor intensive and must be done to a high standard to be useful.
- *Imaging.* MRI may provide some insight; however, these studies are usually small due to logistic problems and, similar to psychometric testing, many outcomes are usually measured that increase the risk of type 1 error. Our understanding of MRI is rapidly increasing but there is still a degree of disconnect between what is seen on the MRI and functional relevance.

In all these studies, it is important to consider the subject’s age at testing. Some aspects of neurodevelopment such as higher executive function cannot be tested until the child is older. Also, after an injury children will usually “grow into their deficit.” An injury in a particular aspect of brain function will become more apparent as the child develops and lacks that function. This is contrary to the idea that the brain will always have plasticity and recovery.

Confounding. Confounding occurs when an observed association between A and B is not direct or causal, but due to another factor C, which increases the likelihood of both A and B. There are huge issues with confounding in all the observational studies looking at anesthesia and developmental outcome. Children have anesthesia because they are having surgery or an investigational procedure. The surgery or procedure may itself cause injury—for example, the stress response of surgery or poorly managed pain. Also, the condition that warrants surgery may be associated with increased risk of poor neurodevelopmental outcome. This may be obvious in the case of genetic abnormalities or major illnesses, but it can also be more subtle. Children having ear tube insertion may require the tubes because they have shown signs of developmental delay as a result of hearing loss. Alternatively, a child needing dental care may require general anesthesia due to the extent of the previously untreated dental problems or as a result of subtle behavioral problems that make providing dental care without general anesthesia challenging.

Confounding can be reduced by careful sample selection, matching, or statistical adjustments in the analysis, but these measures are never mathematically perfect and thus cannot completely remove the influence of confounding. Importantly, they can only reduce the influence of known confounding factors. The problem of confounding means that, by itself, any association seen in an observational study cannot ever be regarded as anything better than weak evidence for causation. Randomized trials are by far the best way to reduce confounding; however, it is nearly impossible to randomize children to anesthesia or no anesthesia.

Results From Population-Based Clinical Studies. Most, but not all, large population-based studies looking at school grades or readiness for school found evidence for a small difference in school grade or readiness in children that have had anesthesia in early childhood.[115-120] The increase in risk is small and, in fact much smaller than the risk associated with gender or month of birth. Interestingly, the studies do not indicate that exposure at 0 to2 years of age is worse than 2 to 4 years of age, and some find the opposite. As far as frequency of exposure, some show weak evidence for a greater risk with multiple exposure but most have insufficient power to determine if having multiple exposures poses any greater risk than single exposure. Several studies found that surgery reduced the likelihood of readiness for school or poor test performance. These findings have many potential explanations, and may be associated with increased risk of acquiring a specific developmental disorder.

Results From Studies That Look at Specific Developmental Disorders

Most, but not all, studies that identify a diagnosis of a learning or developmental disorder found evidence for an association between anesthesia in early childhood and an increased risk of a diagnosis of a behavioral disorder or learning disability.[121-128] Most of these studies also note that this association is greater with multiple exposures.

Results From Studies That Use Psychometric Testing for Outcomes. There is no clear pattern that links the results of these studies. Many studies find evidence for an association between anesthesia in early childhood and one or two particular domains of psychometric testing. These domains include: language, reading, abstract reasoning, executive function, some aspects of memory, processing speed, fine motor abilities, and some aspects of behavior.[129-132] Some, but not all, find an association with a small reduction in IQ.[117]

Some robust studies such as PANDA found no evidence for an association with any deficit.[133] The only trial to report an outcome (the GAS trial) found no evidence for a difference in IQ and a range of other psychometric tests of children tested at age 2 or age 5 after being randomized to either general or awake regional anesthesia for hernia repair.[134]

Summary and Recommendations. In spite of strong animal evidence, there is inconsistent human evidence for an association between anesthesia in early childhood and a range of later neurodevelopmental outcomes. A causal relationship cannot be ruled out; however the human evidence that these associations could be casual is very weak. These associations could be simply explained by confounding. Clinical decisions need to be made in the context of the preclinical and clinical data. Currently, this is an imprecise task; however as further data emerge, the task will become clearer. Most pediatric anesthesia societies currently recommend that surgery not be delayed even in neonates because of what is still a theoretical risk of neurotoxicity and that anesthetic technique should not be altered. Some recommend delaying nonurgent procedures. However, very few purely elective procedures are done in children; delaying procedures is nearly always associated with an increased material risk inherent in not treating the condition that warranted the procedure. Finally, even if surgery is postponed, there are no data to indicate how long any such delay should be. As a result of these conflicting data and while not all agree that neurotoxicity should be included as part of informed consent, anesthesiologists should be prepared to discuss the potential risk of neurotoxicity with parents if they are asked or concerns are expressed. The discussion should include a review of the implications of delaying a procedure.

Ongoing Uncertainties. There are almost no human data specifically examining the impact of prolonged exposures. Two recent studies have identified the range of durations of anesthesia in children in the United States and the majority of these children have had anesthesia for a duration of an hour or less.[135,136]

Apart from the issue of anesthesia neurotoxicity, there is also growing evidence that neonates having major surgery do have a substantially increased risk of neurologic injury and poor neurologic outcome.[137,138] This observation may be completely unrelated to the anesthesia toxicity observed in preclinical studies. It may be partly explained by the considerable comorbidities that these children have; but it is plausible that the injury may also be related to a variety of other factors in the perioperative period such as cerebral perfusion, with or without hypotension, inflammation, hypoxia, hypercarbia, stress, and pain. While the concerns may not be directly related to administration of an anesthetic, the other potential causes for perioperative neurologic injury must be considered and addressed by the anesthesiologist.

It is clear that neonates have vulnerable brains and much more work needs to be done to identify optimal perioperative care for them.

Perioperative Management

PREOPERATIVE EVALUATION

Preoperative evaluation is an essential component of perioperative management. It is aimed to evaluate (1) the child's medical conditions, (2) the needs of the planned surgical or diagnostic procedure, and (3) the psychological context of the child and family. If indicated, this evaluation should be complemented with specific preoperative tests as well as other specialty consultations. The timing of preanesthesia consultation depends on the patient's condition and the type of surgery. It can be strongly influenced by the institutional organization, and demographic and geographic characteristics. Patients with significant medical conditions should be evaluated well in advance of elective surgery to allow sufficient time for appropriate planning and any optimization of medical conditions to decrease perioperative risk. A preanesthesia visit conducted before surgery will also benefit children without notable comorbidities (ASA I and II status) since it offers a meaningful opportunity to provide the child and family with detailed and individualized information on perioperative management which, in turn, can decrease both procedure- and anesthesia-related anxiety. Conducting this interview several days before anesthesia is a legal obligation in several countries to obtain informed consent.

The medical history should have a particular focus on medications, details of previous anesthesia experiences, and family history. Obtaining this information from the child's pediatrician is very helpful when hospital chart reviews are not available. Physical examination includes a thorough assessment of the airway, cardiovascular, respiratory, and nervous systems along with the hydration state of the child. Routine preoperative tests do not make an important contribution to the process of perioperative assessment and management of the patient by the anesthesiologist.[139,140] Although decision-making parameters for specific preoperative tests or for the timing of these tests cannot be adequately determined by current literature,[140] the anesthesiologist should order specific preoperative investigations related to suspected conditions (e.g., the presence of congenital heart disease), which may modify perioperative management and outcome; or conditions (e.g., asthma) in which introduction of a specific treatment could decrease perioperative risks.[139,140] Routine requests for preoperative electrocardiograms (ECG) are not recommended for healthy children. There is, nevertheless, an ongoing controversy about the need for routine neonatal screening for long QT syndrome (LQTS).[141,142] Indeed, LQTS is the leading suspected cause of sudden infant death, and mortality can be decreased by pharmacologic treatment.[143] Since both perioperative stress and a number of anesthetics can lengthen QT interval, performing ECG in neonates and infants under 6 months of age may be an option.[144] The routine use of preoperative chest radiographs should be abandoned especially in view of the harmful effects of ionizing radiation.[140,144] In contrast, a pregnancy test is recommended in all females of childbearing age after proper consent is obtained.[140,144]

The Child With an Upper Respiratory Tract Infection

Upper respiratory tract infections (URIs) are very frequent in childhood with an annual incidence of up to 6 to 8 episodes in infants and preschool children.[145] They usually last for 7 to 10 days, but symptoms may persist for up to 3 weeks. More than 200 viruses have been shown to be associated with URI.[146] The viral invasion of the respiratory mucosa leads to an inflammatory response that results in airway edema and increased secretions.[147] Bronchial hyperreactivity, resulting primarily from the impact of the viral infection on the autonomic nervous system, may persist for up to 6 weeks or longer, well beyond the disappearance of clinical symptoms.[145] Therefore a child with a URI is a major challenge for pediatric anesthesia.[145,148] The most common perioperative respiratory adverse events (PRAEs) associated with URI are: laryngospasm, bronchospasm, breath holding, atelectasis, arterial oxygen desaturation, bacterial pneumonia, and unplanned hospital admission.[149] Fortunately, the incidence of serious PRAEs in children with "common cold" is low.[145]

During the preanesthesia visit, the anesthesiologist should assess the patient for an underlying respiratory illness and identify the risk factors associated with PRAE. These risk factors can be related to the child itself, the specific risks of the anesthesia procedure, or surgery specific factors. Children presenting with signs of serious URI, including fever, productive cough, green runny nose, or otitis media, are at increased risk for PRAE.[150] Infants with respiratory syncytial virus infection present a particularly high-risk group during perioperative management.[151] The anesthesiologist should also elicit any history or signs of primary pulmonary morbidity, such as bronchial asthma, prematurity, and bronchopulmonary dysplasia, cystic fibrosis, and pulmonary hypertension. Passive smoke exposure should also be considered. The anesthesia- and surgery-specific risk factors are most important with instrumental manipulation of the airway such as with bronchoscopy and endotracheal intubation.[145,150] Ear, nose and throat, and eye surgery as well as upper abdominal and thoracic surgeries also increase the risk of PRAE.

The question of whether to cancel a procedure in a child with URI and, if so for how long, is difficult to answer and is influenced by many factors (Fig. 77.10). There is now an increasing expert consensus that it is not necessary to postpone a surgical procedure for 6 weeks after any URI in children.[145,148] Indeed, given the high annual incidence of URI in children, such an approach could even lead to postponing surgery indefinitely. Recent recommendations emphasize an approximately 2-week-long time lag between the resolutions of clinical symptoms and anesthesia.[145]

Several approaches can be taken to decrease the incidence of PRAE in children with URI. Premedication with an aerosol of salbutamol has been shown to be effective in both the prevention and treatment of perioperative bronchospasm in children with bronchial hyperreactivity.[152] While intravenous lidocaine (1 mg/kg) has also been proposed to decrease the incidence of PRAE, current evidence does not support this approach.[145] Induction of anesthesia through an intravenous approach with propofol has been suggested to result in a lower incidence of PRAE in children with URI when compared to inhalational induction.[150] Endotracheal intubation in patients with bronchial hyperreactivity has been shown to be associated with a higher incidence of PRAE when compared with ventilation via a face mask or LMA.[150] Last but not least, several lines of investigations point to the anesthesiologist's experience as an important factor to prevent PRAE.[145]

PERIOPERATIVE ANXIETY IN CHILDREN

A majority of children experience significant anxiety and stress before anesthesia.[153] There is some evidence to suggest an association between preoperative anxiety and adverse postoperative outcomes, including emergence delirium, increased analgesic requirement, and negative behavioral changes.[154,155] In general, fear in children can be related to a number of factors including parental separation, an unfamiliar and threatening hospital environment, painful procedures, the operation itself, and anesthesia.[155] The preanesthesia visit provides an opportunity to identify the contribution of each of these factors, and to discuss the magnitude of preoperative anxiety as well as to plan interventions aimed at decreasing anxiety levels.[154,155] The planning of these interventions has to take into account the age-specific developmental differences in how children react to the stress of anesthesia and surgery. Infants up to 9 months of age are less prone to separation anxiety, and will most probably accept parental surrogates (including soothing voices, gentle rocking, and being held).[156] Separation anxiety is the greatest problem in children between 1 and 3 years of age. Some, but not all, these children may respond to distraction techniques such as toys and stories. While parental presence at anesthesia induction has been advocated in this population, recent studies do not support routine parental presence as the optimal means of reducing anxiety.[157] In addition to being frightened about what is to take place, children between 3 and 6 years of age have concerns about body mutilation and may require reassurance.[155] Preoperative play therapy is especially useful in this age group. Children between 7 and 12 years of age usually require more explanation and wish to actively participate in their perioperative course.

Videos, leaflets, and interactive computer applications are very helpful in this population. Evaluating anxiety in adolescents is particularly difficult. Despite their outwardly calm appearance, teenagers can experience high anxiety and this may steadily increase on their way from the preoperative holding area to the operating room. Risk factors to predict higher anxiety in this group include increased baseline anxiety, depression, somatizing problems, and a fearful temperament.[158]

There is a large variety of different play therapies and behavioral interventions aimed to reduce perioperative anxiety in children. Prehospitalization programs, including tours of the hospital and the operating room, videos, leaflets, and other interactive books and apps should be implemented several days before surgery to achieve the desired effects.[156,159] On the day of intervention, several distraction techniques, including tablets, arrival to the operating room in toy cars, etc., has been shown to be equivalent or even superior to pharmacological premedication in several studies.[160,161] Hypnosis, music, and nonaggressive lighting can also be used to provide a calm and soothing environment for the child upon arrival to the operating room.[155]

Various drugs can be used for pharmacological reduction of anxiety in children.[155,162] In the absence of an intravenous line, the most commonly used routes are the oral, nasal, and rectal routes in decreasing order of acceptability by most children. Midazolam is the most commonly used benzodiazepine for premedication because of its desirable profile of safety and efficacy. It is usually administered orally at a dose of 0.5 mg/kg (up to a maximum of 15 mg); after administration, sedation and anxiolysis are achieved within approximately 20 minutes. It can also be administered by the intravenous route (0.05-0.1 mg/kg) as well as by the intranasal (0.3 mg/kg) and the rectal (0.5 mg/kg) route.[154] Potential limitations of its use as an ideal drug for premedication is the potential for prolonged effect and for paradoxical reactions.[154] Agonists of α_2 adrenergic receptors are increasingly used for premedication. Clonidine can be administered both orally (4 µg/kg) or intranasally (4 µg/kg) and, albeit it has a relatively long onset time (45 minutes), its analgesic and anesthetic-sparing properties are very advantageous. Dexmedetomidine has a shorter onset and duration of action when compared with clonidine and is an interesting alternative for premedication. It has a low bioavailability when given orally (~15%) but may be more effective when given intranasally.[158] Ketamine is highly lipid soluble and is rapidly absorbed after either oral, intranasal, intramuscular, or intravenous administration. Onset of sedation occurs after 15 to 20 minutes following oral intake (5-8 mg/kg).[155] Intramuscular administration of ketamine (4-5 mg/kg) is especially useful in uncooperative and combative children when the procedure cannot be delayed or rescheduled. Premedication with ketamine, however, can be associated with hypersalivation, hyperventilation, hallucinations, and with an increased incidence of emergence delirium.[155,162] Fentanyl is rapidly absorbed by the transmucosal route and can be used for premedication as a pleasant tasting lollipop. The bioavailability by this route is 33% but is reduced if the lollipop is chewed or swallowed.[162] Side effects of fentanyl premedication include vomiting, pruritus, and respiratory depression.

PREOPERATIVE FASTING

Preoperative fasting minimizes the risk of pulmonary aspiration of gastric contents during anesthesia. Most national guidelines recommend the "6-4-2 rule" meaning a minimum of 6-hour-long fasting for solid foods, 4-hour-long fasting for breast milk, and a 2-hour-long fasting for clear fluids. These guidelines do not make any distinction between adults and children[163] and are primarily based on expert opinion, and are not backed by solid clinical evidence.[163] Adhering to these guidelines in children may pose several problems. First, in reality, fasting times often end up being much longer, and it is not uncommon to see young children fasting for clear liquids up to 12 hours or more prior to anesthesia induction.[164-166] In addition to the obvious discomfort related to hunger and thirst, these prolonged fasting times may result in hypoglycemia, metabolic acidosis, dehydration, and cardiovascular instability.[164,165] The incidence of pulmonary aspiration in otherwise healthy children is very low ($1\text{-}2/10^4$), and increasing evidence indicates that liberal clear fluid intake, at least until the point when premedication is given, does not result in increased residual gastric volume, or increase the incidence of pulmonary aspiration.[164,165] Therefore the currently applied fasting guidelines may need reevaluation. The new European consensus statement on fasting in children recommends a 1-hour-long fasting after clear fluid intake.

ANESTHESIA INDUCTION

The method of inducing anesthesia is determined by a number of factors including the medical condition of the child, the surgical procedure, the level of anxiety of the child, the child's ability to cooperate and communicate (because of age, developmental delay, or language barrier), and the presence or absence of a full stomach. As discussed above, most children are anxious prior to anesthesia induction and numerous pharmacological and nonpharmacological techniques have been proposed to alleviate this anxiety. Many of the play therapies and/or hypnotic suggestions can be continued during the anesthesia induction. Use of parental presence varies markedly between hospitals. A recent evidence-based review of the existing literature suggests that neither the child's nor the parent's anxiety is alleviated by parental presence upon anesthesia induction.[167] Nevertheless, parental presence may be important with children who have underlying behavioral problems or developmental delay (e.g., autism spectrum disorders, Down syndrome), as well as in children scheduled for repeated procedures. In these circumstances, education of the parents prior to anesthesia induction can be helpful in reducing anxiety for both the parent and child.

Both the parents and the operating room staff should be involved in the perioperative plan and management of aggressive combatant children.[155] These children are particularly anxious; they will rarely cooperate with behavioral therapies used prior to anesthesia and will often refuse to take any pharmacological premedication. Often they have had previous anesthetics; the parents can be extremely helpful in describing what works best for them. For these children, intranasal administration of premedication may be beneficial. In the absence of an existing intravenous line, intramuscular administration of ketamine (4-5 mg/kg) or inhalational induction using high concentrations of sevoflurane can be a helpful option to induce anesthesia in this population. These latter approaches necessitate physical restraint which raises ethical, legal, and practical problems. To be the most effective, restraining and holding should not be left to the parents alone, but should be performed under the direction of experienced anesthesia staff. Relative contraindications to this approach include lack of consent by parents or staff, failure to exhaust all other techniques, and when the restraint-induced stress could significantly worsen the child's state (e.g., significant cardiac comorbidities).[155,168] The option of postponing elective surgery for these children should always be considered.

The two most common anesthesia induction techniques in children are inhalational and intravenous induction. The causal relationship between the type of anesthesia induction and PRAE is poorly documented. In children with a high risk of PRAE, a retrospective study suggested a benefit of intravenous induction,[150] and this has recently been further substantiated by a randomized trial.[167] It is, nevertheless, important to note that these studies were focused only on PRAE in a group of children with increased risk for PRAE and many other factors, including the child's acceptance/fear for the establishment of an intravenous line as well as the feasibility of this approach with relative ease, should also be considered. Therefore when deciding on the induction technique, care should be taken to weigh all the relevant factors.[169]

The use of RSI to prevent pulmonary aspiration of gastric content is based on experiences in the adult population. Direct extrapolation of the "classical form" of this technique to pediatric populations may not always be the correct choice due to the anatomical and physiological differences between adults and young children.[170-172] While the classic RSI relies on adequate preoxygenation, this often cannot be achieved in uncooperative children. Even in cooperative children, preoxygenation is not as effective as it is in adult patients. Importantly, due to the low FRC, even brief periods of apnea in the absence of positive pressure ventilation can lead to profound hypoxemia and related bradycardia in this population. Administration of an intravenous agent necessitates an intravenous line, something difficult to achieve in the agitated child. Application of cricoid pressure can easily distort the airway in young children thereby rendering the visualization of glottic structures difficult. Most important, these factors may lead to a higher incidence of unsafe actions such as forced mask ventilation and unsuccessful intubation attempts.[171,172] Therefore to balance the risk of pulmonary aspiration with the much more prevalent risk of hypoxemia, controlled forms of the RSI technique have become increasingly popular among pediatric anesthesiologists.[170-172] Importantly, regurgitation and vomiting with aspiration are mostly elicited by direct laryngoscopy under light anesthesia and incomplete muscle paralysis.[173-175] While the possibility of mask induction should always be evaluated, intravenous access has to be considered mandatory in “at-risk” children.[172] Intraosseous access is a suitable alternative in this population where intravenous access cannot be established.[176] In the presence of an existing intravenous line, rapid induction of adequate hypnosis and profound muscle paralysis using a nondepolarizing muscle relaxant, gentle mask ventilation with a maximum airway pressure of 12 cm H_2O until endotracheal intubation can be performed. The adoption of such a “controlled” approach may reduce the potentially significant risk of hypoxemia while providing rapid intubating conditions.[170]

AIRWAY MANAGEMENT AND VENTILATION

Airway Management

Preoperative evaluation of the airway should be based on both the child’s medical record and clinical evaluation. A wide range of syndromic and genetic conditions and congenital malformations are associated with potential airway problems, especially those involving facial dysmorphias.[177,178] History of birth complications, obstructive sleep apnea, head and neck trauma, previous surgery, and related airway management must also be considered. During the physical examination, the anesthesiologist should check for facial dysmorphias, signs of stridor, dysphonia, swallowing disorders, difficulty in breathing, difficulty in speaking, and hoarseness.[178] There are a large number of difficult airway predictors in children but their applicability, sensitivity, and specificity vary greatly in the clinical setting. Among them, mandibular protrusion, Mallampati’s classification, movement of atlantooccipital joint, reduced mandibular space, and increased tongue thickness have all been shown to be good predictors of airway problems.[179,180] Other reported risk factors are age less than 1 year, ASA II-IV status, obesity, and maxillofacial and cardiac surgery.[181]

Appropriately performed mask ventilation is a critical component of pediatric airway management. Anesthetized children are particularly prone to upper airway collapse; it can be easily relieved by a combination of moderate head tilt, chin lift, jaw thrust, and the application of continuous positive airway pressure.[182,183] The combination of these maneuvers with lateral decubitus position can further improve airway patency.[184] Additionally, both oropharyngeal and nasopharyngeal airway devices can be used during spontaneous or positive pressure mask ventilation to further relieve airway obstruction caused by the posterior displacement of the tongue in anesthetized children.[185,186]

A large variety of supraglottic airway devices are now commonly used in pediatric anesthesia. The two most popular among these are the classic laryngeal mask airway (LMA) and the LMA ProSeal.[183] Both devices have comparable safety and efficacy profiles in pediatric populations.[187] Increasing evidence suggests that the use of the LMA in children is associated with a decreased incidence of perioperative respiratory complications when compared to endotracheal tube insertion.[188]

Direct laryngoscopy is still the most frequently used technique for intubation in children. Because of the diverse ages and size of the pediatric patient population, any hospital that cares for children must have a full selection of both curved and straight laryngoscope blades to ensure that the blade most appropriate for the child is readily available. In general, since the epiglottis is more “U” shaped in young children and it may lie across the glottic opening, straight blades are routinely used in neonates and toddlers to directly elevate the epiglottis and visualize the vocal cords. Older children can be managed with either curved or straight blades. An ever-increasing number of devices have been developed over the past decade to facilitate endotracheal intubation.[189] Among them, videolaryngoscopy has been initially introduced as an aid for difficult airway management, and it may even replace the use of flexible fibroscopy in an increasing number of indications.[190] The use of videolaryngoscopy in everyday routine airway management is also increasing. Indeed, these devices enable a better and faster glottic visualization thereby reducing the time of intubation, the number of attempts, as well as dental trauma. It is, however, important to note that each type of videolaryngoscope requires a particular technique, and that technique can vary considerably between devices.[189] While awake fiberoptic intubation is generally considered as the gold standard for the known or anticipated difficult airway in adults, this option is usually not feasible in children due to the need for significant cooperation during the procedure. Most pediatric anesthesiologists prefer the use of inhalational induction in the case of predicted difficult airway and perform flexible fibroscopy-aided intubation under spontaneous ventilation in the anesthetized child.[191]

The use of cuffed endotracheal tubes has become increasingly common in neonates, infants, and young children.[183] Historically, uncuffed endotracheal tubes were recommended in children less than 8 years of age, because it was thought that the narrowest part of the airway was the cricoid ring and to minimize potential cuff-induced damage of the tracheal mucosa as well as to allow reduction of air flow resistance by inserting a larger size tube.[192] Airway trauma can also occur when using an uncuffed tube with acceptable leak pressures. Moreover, a higher incidence of laryngospasm with the use of uncuffed tubes has also been reported, and there is no data of increased subglottic airway trauma when cuffed versus uncuffed tubes are used.[178] A cuffed tube with no leak may also allow a more accurate estimate of end tidal carbon dioxide (CO_2) concentrations and avoid pollution of the operating room. Last but not least, the relatively frequent need for changing the endotracheal tubes due to significant leak associated with insertion of an uncuffed tube is also virtually eliminated by using cuffed tubes. Repeat laryngoscopy is avoided since inflating the cuff may allow insertion of a smaller tube and using the cuff to occlude the airway without the need for replacing the tube with a larger tube. At the same time, care must be exercised when using a cuffed tube since smaller diameter tracheal tubes may become more easily kinked or obstructed by secretions.

The incidence of an unexpected difficult pediatric airway is low compared to adults but may still result in major morbidity and mortality.[193] As a result, although sparse high-quality evidence is available on pediatric airway management, there is a general expert consensus that adult guidelines are not designed for use in young children. The recent international guidelines for the management of unanticipated difficult airway in pediatric practice is the result of a Delphi panel expert discussion and is focusing on airway management in children between 1 year and 8 years of age.[193] Three scenarios are identified: (a) difficult mask ventilation, (b) difficult tracheal intubation, and (c) cannot intubate and cannot ventilate in paralyzed anesthetized children. Detailed guidance for each of these scenarios is provided (Fig. 77.11). These guidelines were developed specifically for the nonspecialist anesthesiologist and can be adapted to the specificities of the anesthesia service taking care of children. Most importantly, each area for anesthetizing children should have access to a specific difficult airway trolley with appropriate equipment as well as a written plan of difficult airway algorithms along with a plan for whom to call for help, should an anesthesiologist need additional help in managing an unanticipated difficult pediatric airway.[194]

The Child With Stridor

A child with intrathoracic airway obstruction has expiratory stridor and prolonged expiration (e.g., bronchiolitis, asthma, intrathoracic foreign body).[195] In contrast, a child with extrathoracic upper airway obstruction has inspiratory stridor (e.g., epiglottitis, laryngotracheobronchitis, laryngeal, subglottic foreign body). When agitated or crying, such children exhibit dynamic collapse of the airway (Fig. 77.12), which can significantly worsen airway obstruction and lead to respiratory failure and hypoxemia. Therefore events that can upset the child, such as drawing of blood for analysis of gases, venipuncture for blood tests, and separation from parents, must be minimized. The difficult-airway cart should also be present. The surgical team should be mobilized and prepared to perform an emergency tracheotomy should total airway obstruction occur and mask ventilation or tracheal intubation not be possible.

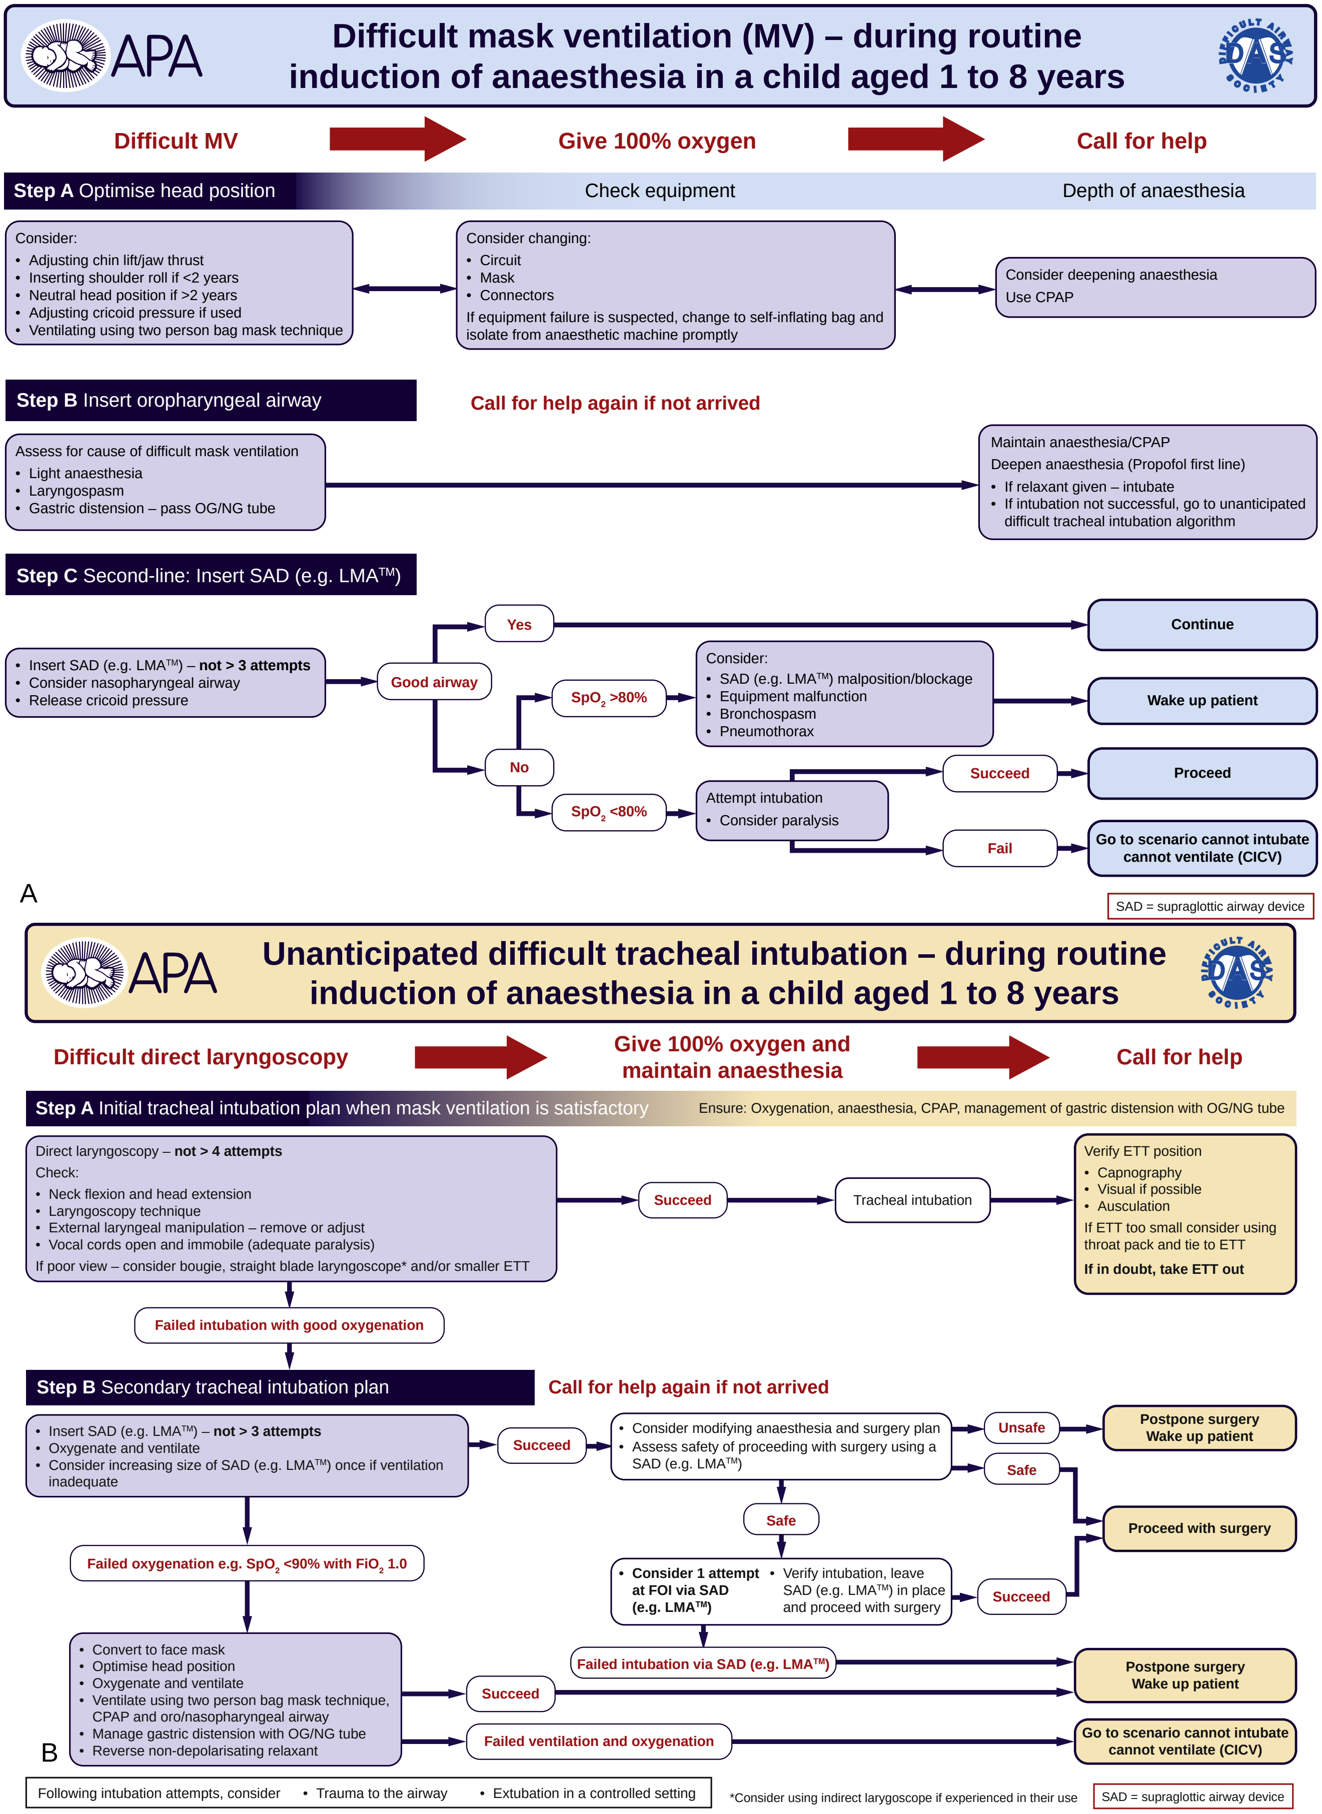
When inducing anesthesia in a child with stridor the following is suggested. To minimize upsetting the child, the child is brought to the operating room with the mother or father, who holds the child during induction (preferably lying down in a semi-upright position). Induction of anesthesia with sevoflurane in oxygen by mask is the preferred method because maintaining spontaneous respirations is critical. If the stridor worsens or mild laryngospasm occurs, then the pop-off valve is sufficiently closed to develop 10 to 15 cm H_2O of positive end-expiratory pressure (PEEP). This procedure relieves most instances of airway obstruction caused by dynamic collapse of the airway and loss of pharyngeal muscle tone when the child attempts to inspire against an obstructed airway (Fig. 77.13). As the level of anesthesia deepens, gentle assistance with ventilation may be necessary; however, maintaining spontaneous respiratory effort is important if possible.

Any child with airway obstruction will have a long, slow induction of anesthesia before becoming sufficiently anesthetized to permit laryngoscopy and tracheal intubation. The issue of a full stomach is secondary to the airway problem. Rapid induction of anesthesia and paralysis is contraindicated in these children. A child with laryngotracheobronchitis or epiglottitis usually requires an uncuffed tracheal tube that is 0.5 to 1.0 mm internal diameter smaller than normal (Table 77.6); the use of a stylet facilitates its insertion.

Ventilation Strategies

Details of respiratory care, ventilator modalities, and setting are reviewed in Chapter 41 (Respiratory Care). There is a paucity of evidence to guide optimal pediatric ventilation practices for patients either with or without lung injury.[196] As a result, when pediatric anesthesiologists determine ventilator settings deemed optimal for any individual patient, they take into account available adult data, the age-specific anatomic and physiological differences between the young and the adult lung, as well as their own personal experience. In adults, it is increasingly recognized that mechanical ventilation can cause injury to the lung (ventilator-induced lung injury [VILI]) even in healthy patients, and the importance of volutrauma via higher than physiologic tidal volumes in this pathology is now established.[197] The clinical relevance of VILI in pediatric populations is not clear. No study has examined the relationship between modalities of mechanical ventilation during pediatric anesthesia and patient outcome. A recent meta-analysis demonstrated no relationship between tidal volume and mortality in mechanically ventilated patients in the pediatric ICU irrespective of the severity of disease.[198] Therefore it may be that the susceptibility to VILI is age-dependent.[196] No evidence-based recommendation can be made on the optimal tidal volume in pediatric ventilation; however, it may be argued that a tidal volume between 6 and 10 mL/kg is justifiable but a tidal volume more than 10 mL/kg should be avoided.[199] The effects of inspiratory pressures in pediatric patients with healthy lungs have not been studied but data from children with acute lung injury suggest a direct relationship between peak inspiratory pressures and mortality.[200] Thus pressure-controlled ventilation (PCV) with a decelerative flow may be favored over volume-controlled ventilation with a continuous inspiratory flow pattern.[196,201] One obvious disadvantage of PCV is the lack of volume guarantee since the resulting tidal volume will depend on the compliance and the resistance of the respiratory system. Monitoring pressure and flow curves are therefore essential components of mechanical ventilation. New ventilators are now providing us with ventilatory modes combining PCV with volume guarantee.[201]

PEEP is an important part of protective lung ventilation strategies, and is aimed to prevent atelectasis via stabilization of recruited alveoli.[196,201] The optimal PEEP in pediatric ventilation is undetermined but is routinely set at a level of 5 cm H_2O.[201] Higher levels of PEEP (exceeding 10-15 cm H_2O) may be necessary in case of lung injury. However, care should be exercised when increasing the PEEP to avoid hemodynamic compromise as a result of the higher intrathoracic pressure. PEEP should always be carefully titrated



Difficult mask ventilation (MV) – during routine induction of anaesthesia in a child aged 1 to 8 years

Difficult MV → **Give 100% oxygen** → **Call for help**

Step A Optimise head position — Check equipment — Depth of anaesthesia

Consider:
- Adjusting chin lift/jaw thrust
- Inserting shoulder roll if <2 years
- Neutral head position if >2 years
- Adjusting cricoid pressure if used
- Ventilating using two person bag mask technique

Consider changing:
- Circuit
- Mask
- Connectors

If equipment failure is suspected, change to self-inflating bag and isolate from anaesthetic machine promptly

Consider deepening anaesthesia
Use CPAP

Step B Insert oropharyngeal airway

Call for help again if not arrived

Assess for cause of difficult mask ventilation
- Light anaesthesia
- Laryngospasm
- Gastric distension – pass OG/NG tube

Maintain anaesthesia/CPAP
Deepen anaesthesia (Propofol first line)
- If relaxant given – intubate
- If intubation not successful, go to unanticipated difficult tracheal intubation algorithm

Step C Second-line: Insert SAD (e.g. LMA^{TM})

- Insert SAD (e.g. LMA^{TM}) – **not > 3 attempts**
- Consider nasopharyngeal airway
- Release cricoid pressure

Consider:
- SAD (e.g. LMA^{TM}) malposition/blockage
- Equipment malfunction
- Bronchospasm
- Pneumothorax

Attempt intubation
- Consider paralysis

Go to scenario cannot intubate cannot ventilate (CICV)

SAD = supraglottic airway device

Unanticipated difficult tracheal intubation – during routine induction of anaesthesia in a child aged 1 to 8 years

Difficult direct laryngoscopy → **Give 100% oxygen and maintain anaesthesia** → **Call for help**

Step A Initial tracheal intubation plan when mask ventilation is satisfactory — Ensure: Oxygenation, anaesthesia, CPAP, management of gastric distension with OG/NG tube

Direct laryngoscopy – **not > 4 attempts**
Check:
- Neck flexion and head extension
- Laryngoscopy technique
- External laryngeal manipulation – remove or adjust
- Vocal cords open and immobile (adequate paralysis)

If poor view – consider bougie, straight blade laryngoscope* and/or smaller ETT

Verify ETT position
- Capnography
- Visual if possible
- Auscultation

If ETT too small consider using throat pack and tie to ETT

If in doubt, take ETT out

Failed intubation with good oxygenation

Step B Secondary tracheal intubation plan

Call for help again if not arrived

- Insert SAD (e.g. LMA^{TM}) – **not > 3 attempts**
- Oxygenate and ventilate
- Consider increasing size of SAD (e.g. LMA^{TM}) once if ventilation inadequate

- Consider modifying anaesthesia and surgery plan
- Assess safety of proceeding with surgery using a SAD (e.g. LMA^{TM})

Postpone surgery
Wake up patient

Proceed with surgery

- **Consider 1 attempt at FOI via SAD (e.g. LMA^{TM})**
- Verify intubation, leave SAD (e.g. LMA^{TM}) in place and proceed with surgery

Failed oxygenation e.g. SpO$_2$ <90% with FiO$_2$ 1.0

Failed intubation via SAD (e.g. LMA^{TM})

Postpone surgery
Wake up patient

- Convert to face mask
- Optimise head position
- Oxygenate and ventilate
- Ventilate using two person bag mask technique, CPAP and oro/nasopharyngeal airway
- Manage gastric distension with OG/NG tube
- Reverse non-depolarising relaxant

Failed ventilation and oxygenation

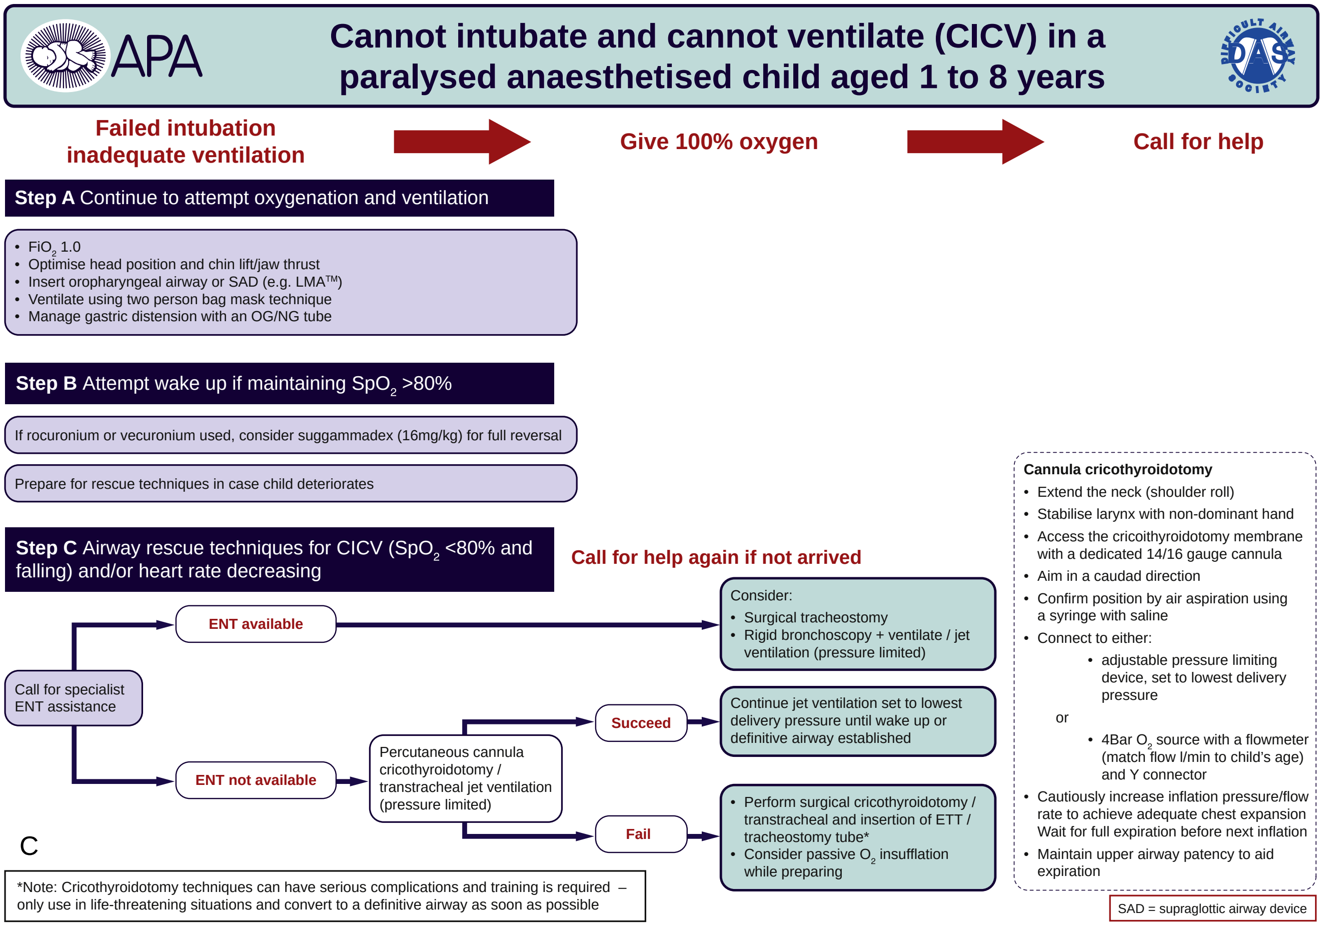
Go to scenario cannot intubate cannot ventilate (CICV)

Following intubation attempts, consider • Trauma to the airway • Extubation in a controlled setting

*Consider using indirect larygoscope if experienced in their use

SAD = supraglottic airway device

Fig. 77.11 Difficult airway algorithms in children aged 1 to 8 years. (A) Guideline for the management of unanticipated difficult mask ventilation. (B) Guideline for the management of the unanticipated tracheal intubation during routine induction of anesthesia.



APA

Cannot intubate and cannot ventilate (CICV) in a paralysed anaesthetised child aged 1 to 8 years

Failed intubation inadequate ventilation → **Give 100% oxygen** → **Call for help**

Step A Continue to attempt oxygenation and ventilation

- FiO_2 1.0
- Optimise head position and chin lift/jaw thrust
- Insert oropharyngeal airway or SAD (e.g. LMA™)
- Ventilate using two person bag mask technique
- Manage gastric distension with an OG/NG tube

Step B Attempt wake up if maintaining SpO_2 >80%

If rocuronium or vecuronium used, consider suggammadex (16mg/kg) for full reversal

Prepare for rescue techniques in case child deteriorates

Step C Airway rescue techniques for CICV (SpO_2 <80% and falling) and/or heart rate decreasing

Call for help again if not arrived

Call for specialist ENT assistance

ENT available → Consider:
- Surgical tracheostomy
- Rigid bronchoscopy + ventilate / jet ventilation (pressure limited)

ENT not available → Percutaneous cannula cricothyroidotomy / transtracheal jet ventilation (pressure limited)

Succeed → Continue jet ventilation set to lowest delivery pressure until wake up or definitive airway established

Fail →
- Perform surgical cricothyroidotomy / transtracheal and insertion of ETT / tracheostomy tube*
- Consider passive O_2 insufflation while preparing

Cannula cricothyroidotomy
- Extend the neck (shoulder roll)
- Stabilise larynx with non-dominant hand
- Access the cricoithyroidotomy membrane with a dedicated 14/16 gauge cannula
- Aim in a caudad direction
- Confirm position by air aspiration using a syringe with saline
- Connect to either:
    - adjustable pressure limiting device, set to lowest delivery pressure

  or
    - 4Bar O_2 source with a flowmeter (match flow l/min to child's age) and Y connector
- Cautiously increase inflation pressure/flow rate to achieve adequate chest expansion Wait for full expiration before next inflation
- Maintain upper airway patency to aid expiration

C

*Note: Cricothyroidotomy techniques can have serious complications and training is required – only use in life-threatening situations and convert to a definitive airway as soon as possible

SAD = supraglottic airway device

Fig. 77.11—cont'd (C) Guideline for the management of can't intubate, can't ventilate *(CICV)* when there is a failure to intubate and failure to adequately ventilate an anesthetized and paralyzed child. (From Black AE, Flynn PE, Smith HL, et al. Development of a guideline for the management of the unanticipated difficult airway in pediatric practice. *Paediatr Anaesth.* 2015;25[4]:346–362.)

to achieve an optimal balance between hemodynamics and ventilation.[196]

Equipment dead space, defined as any portion of the anesthesia circuit in which there is a bidirectional gas flow without gas exchange, is more significant in children than adults.[201] The circuit dead space adds to the anatomic and physiologic dead space and, as a result, particularly in smaller patients may be the greatest contributor to an increase in the dead space to tidal volume ratio which, in turn, can lead to an increase in $PaCO_2$.[202] Therefore every effort should be made to minimize apparatus dead space, especially in neonates and infants.

EQUIPMENT AND MONITORING

Standards for basic anesthesia monitoring are the same for adults and children. These monitoring modalities include the presence of qualified anesthesia personnel in the operating room during the whole duration of the procedure as well as equipment to monitor the patient's oxygenation, ventilation, circulation, and temperature. The need for additional monitoring, above these minimal requirements, will depend on the child's condition and on the type of surgery. Much of the equipment used in adults is not suitable for children. Pediatric anesthesia may involve caring for children that range from a neonate of a few hundred grams weight to an adult-sized adolescent; therefore there should be a full range of sizes of pediatric equipment available and an anesthesiologist with pediatric anesthesia experience should be responsible for the organization of these items.[203] A resuscitation cart with equipment appropriate for pediatric patients of all ages, including pediatric defibrillation paddles, is needed. Resuscitation cardiac drugs should be available in appropriate concentrations and a written pediatric dose schedule for these drugs should also be included. Pediatric-specific cognitive aids for the diagnosis/treatment of the most common emergencies and critical conditions should be immediately available both in the operating room and in the PACU. Airway equipment for all pediatric age groups should include ventilation masks, supraglottic airway devices, tracheal tubes, oral and nasopharyngeal airways, as well as laryngoscopes with pediatric blades. A separate, fully stocked difficult airway cart containing specialized equipment for the management of the difficult pediatric airway along with institution-specific difficult airway algorithm should also be available. A 20% lipid emulsion should readily be accessible to treat local anesthetic systemic toxicity in any location where regional blocks are performed. Most importantly, an anesthesiologist with experience in pediatric perioperative care should be immediately available to evaluate and treat any critical anesthesia event in a child.

There have been considerable improvements and greater options for equipment and monitoring for children over the past decade.[189,204] The development of a large array of videolaryngoscopes has fundamentally changed both the notion of and the approaches to the difficult airway in institutions where these devices are available.[189] Equipment aimed to facilitate the often-challenging venous access in children include near-infrared and ultrasound devices. Near-infrared devices use the principle that near-infrared light penetrates the skin and is principally absorbed by hemoglobin which, in turn, helps to visualize veins of even small diameters. While these devices have been available for several years, there is still a paucity of evidence that they can reduce either the time or the success rate of venous cannulation in children.[189] In contrast, ultrasound-guided central venous access in children is faster, has a higher success rate, and a reduced complication rate compared to traditional landmark techniques, and has consequently become a standard of care.[205] Ultrasound can also be useful for peripheral venous cannulation in children with difficult venous access.[206] Tablets and smartphones can be useful as distraction techniques during venous cannulation and other stressful times for children during the perioperative period.[189,207] An increasing number of pediatric anesthesia *apps* are also available to assist with calculations and algorithms when managing a diverse group of patients and to ensure appropriate drug dosages and equipment selection.[189]

Continuous cardiac output monitoring is also increasingly used in children. Currently available options are based on the principles of Doppler, electrical impedance methods, measures of cardiac output adequacy, or pulse contour analysis. Transesophageal Doppler probes are validated against thermodilution, Fick, and dye dilution techniques for children as small as 3 kg.[208] Changes in thoracic electrical bioimpedance, as a result of changes in blood volume and flow, and blood cell orientation can be used for continuous noninvasive monitoring of cardiac output and other cardiac parameters. The ICON monitor (Cardiotronic/Osypka Medical Inc., La Jolla, CA, USA) is a portable noninvasive

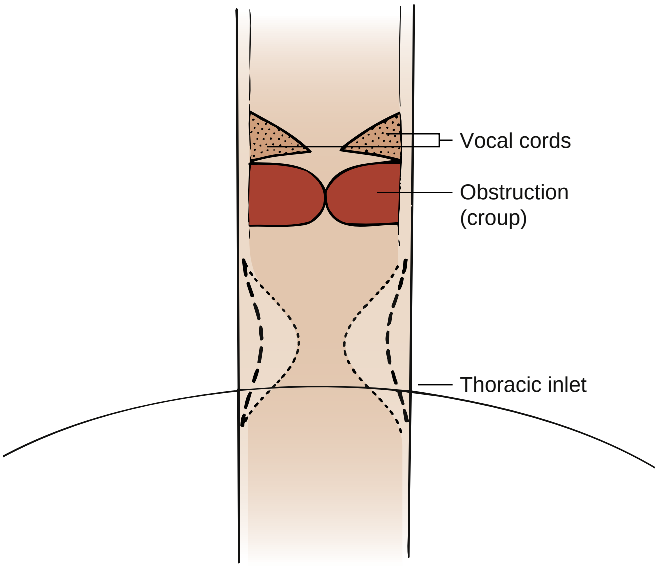


Fig. 77.12 Infants and young children have highly compliant airway structures. With normal respiration, some dynamic collapse of the extrathoracic upper airway occurs *(broken line)*. When a child has upper airway obstruction, as in epiglottitis, laryngotracheobronchitis, or extrathoracic foreign body *(dark brown)*, and struggles to breathe against this obstruction, dynamic collapse of the trachea increases. This increase in dynamic collapse *(dotted line)* augments the mechanical obstruction of the airway. Therefore until the airway is secured, avoiding procedures that will upset the child is important. (Modified from Coté CJ, Lerman J, Anderson BJ, eds. *A Practice of Anesthesia for Infants and Children.* 5th ed. Philadelphia: Saunders; 2013.)

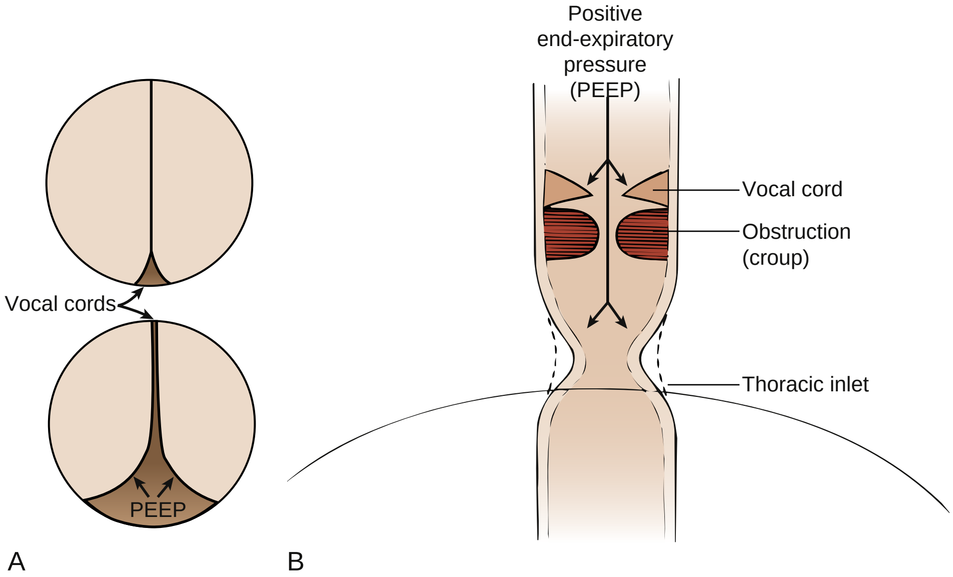

Fig. 77.13 When a child has upper airway obstruction caused by laryngospasm (A) *(top)* or mechanical obstruction (B), application of approximately 10 to 15 cm H_2O of positive end-expiratory pressure *(PEEP) (arrows)* during spontaneous breathing often relieves the obstruction. PEEP helps keep the vocal cords separated (A) *(bottom)* and the airway open (B) *(broken lines)*. If this simple maneuver does not relieve the obstruction, then more vigorous positive-pressure ventilation may be necessary. Airway obstruction caused by the tongue requires insertion of an appropriately sized oral airway.

TABLE 77.6 Recommended Sizes and Distance of Insertion of Endotracheal Tubes and Laryngoscope Blades for Use in Pediatric Patients

Age of Patient	Internal Diameter of Endotracheal Tube (mm)	Recommended Size of Laryngoscope Straight Blade	Distance of Insertion* (cm)
Preterm (<1250 g)	2.5 uncuffed	0	6-7
Full term	3.0-3.5 uncuffed	0-1	8-10
3 months-1 year	3.5-4.0 cuffed	1	11
2 years	4.5-5.0 cuffed	1-1.5	12
6 years	5.0-5.5 cuffed	1.5-2	15
10 years	6.0-6.5 cuffed	2-3	17
18 years	7.0-8.0 cuffed	3	19

*Inserting the endotracheal tube these distances from the alveolar ridge of the mandible or maxilla usually places the distal end of the tube in the midtrachea.

cardiac output monitor that is based on the principle of electrical velocimetry. This device has been validated against the Fick equation, thermodilution, and echocardiography in pediatric populations ranging from neonates to adolescents.[208] Cardiac output monitors based on pulse contour analysis use complex algorithms to calculate cardiac output from the shape of the arterial blood pressure waveform. They usually require calibration based on an arterial line and the majority of these devices have not been validated in children.[189] Pulse oximetry-based noninvasive hemoglobin determination is an appealing possibility but still needs to be validated in pediatric populations.[204]

Near-infrared spectroscopy (NIRS) uses principles similar to those of pulse oximetry to measure tissue hemoglobin oxygenation. NIRS monitoring can be used to monitor oxygenation and thus indirectly, the blood flow and supply-demand relationship in multiple organs, including the brain, liver, kidney, intestines, and muscles. Evidence that NIRS improves outcomes is lacking, as it is for many of the monitoring devices, but there is certainly potential for its use in goal-directed interventions to reduce organ hypoxemia and ischemia.[204,209]

There is so far little evidence that intraoperative EEG monitoring improves outcomes in children. It is, nevertheless, important to note that neuromorbidity, unless overt, is very difficult to detect. BIS monitoring has been successfully used in older children to decrease the total amount of anesthesia drugs delivered and to enhance recovery.[210] The utility of BIS in infants, particularly those less than 6 months old, is questionable as there is little correlation between BIS values and other measures of depth of anesthesia in these populations.[210] More recently developed approaches, such as spectral frequency analysis, could be interesting in this regard but future work is still necessary to validate these methods.[211]

SAFETY ISSUES

Perioperative mortality in neonates and infants is several fold higher when compared to older children.[212] It is important to realize that, in these populations, increased mortality is not synonymous with anesthesia-related mortality, since anesthesia-related death rarely occurs in children who do not have significant associated medical comorbidities. Nevertheless, critical events that could potentially lead to mortality or significant and lasting morbidity can be a direct consequence of anesthesia management. There are three major approaches that can identify adverse outcomes in pediatric perioperative care: (1) institutional audits; (2) closed claims analysis; and (3) large-scale registries of anesthesia-related cardiac arrest. Each of these approaches has strengths and limitations in terms of size, reporting bias, and varying definitions but they all identify young age (i.e., infants), ASA III-V status, and emergency surgery as principal risk factors for critical events. The critical events are most often cardiac and/or respiratory. According to the POCA, the most common causes of perioperative cardiac arrest in children are cardiac in origin including, in a decreasing order of frequency, hypovolemia, myocardial ischemia, hyperkalemia, and sudden arrhythmias.[56] Respiratory causes include laryngospasm, inadequate oxygenation, and difficult intubation.[56] Based on analysis of closed claims, it has been suggested that critical events leading to serious respiratory morbidity have decreased since the introduction of minimal monitoring standards.[213]

There is circumstantial evidence suggesting an association between the level of expertise in pediatric anesthesia and perioperative morbidity. Indeed, the incidence of respiratory complications has been repeatedly reported to be dependent on the anesthesiologist's experience.[150,214-216] There is also a relationship between perioperative complications and the number of pediatric anesthetics provided by the anesthesiologist.[217,218] Specific training for pediatric anesthesia and maintaining a suitable volume of experience of pediatric anesthesia has therefore been recommended for those providing anesthesia care to children.[219,220]

FLUID MANAGEMENT

Perioperative fluid management raises important challenges in pediatric populations. Hypovolemia, often underestimated, is the most common cause of perioperative cardiac arrest in children.[55] Administration of solutes with inappropriate composition or at an exceedingly high rate can also result in significant morbidity and mortality. The rapidly evolving age-specific changes in metabolism, extracellular fluid volume, and fluid turnover do not allow the direct extrapolation of adult guidelines to children, neither do they permit the generation of simplified recommendations that are broadly applicable to all pediatric age groups.

Given these difficulties, the availability of evidence-based recommendations is scarce while expert opinions dominate. Although no unequivocal consensus has been reached between experts, the concept of perioperative fluid management in children has undergone important changes over the past decade.

The three major goals of perioperative fluid management are (1) to meet maintenance requirements; (2) to replace preoperative deficits; and (3) to compensate for ongoing losses occurring during the perioperative period. The most commonly used basic fluid maintenance formula in pediatric anesthesia practice is based on the relationship between physiologic fluid loss and caloric expenditure,[221] and has been evolved into the so-called "4-2-1" rule which is a weight-based formula stating that the hourly fluid requirements of children are 4 mL/kg for the first 10 kg of body weight followed by 2 mL/kg between 10 to 20 kg and 1 mL for each additional kg of body weight above 20 kg.[222] It is widely accepted that this formula overestimates the maintenance requirements for sick children. There is also an ongoing debate on how to compensate for preoperative fluid deficits.[223] The reason behind this incertitude is that perioperative studies to guide and determine optimal fluid status in children are lacking. One of the simplest options to decrease preoperative fluid deficits is to minimize preoperative fasting times for clear liquids.[164] Previously it was recommended to calculate and replace the preoperative fasting deficit based on the "4-2-1" rule, or to provide a bolus of 25 mL/kg for children younger than 3 years of age and 25 mL/kg over 3 years of age. Recently, the German guidelines, widely adopted in Europe, state that "the background infusion may be initiated with an initial infusion rate of 10 mL/kg/h and be adjusted to the actual requirement during the further course."[224] Moreover, in case of apparent clinical signs of dehydration, these guidelines recommend 10 mL/kg fluid bolus for every percent of estimated dehydration.[224] The amount of fluids needed for ongoing losses during the perioperative period largely depends on the type of procedure as well as on the pathological state of the child. It can easily be as high as 10 to 15 mL/kg/h and, in some specific cases such as burns or extensive neonatal abdominal surgery, can exceed 50 mL/kg/h.[223] Individualized goal-directed fluid management using a combination of hemodynamic monitoring approaches is of utmost importance to meet these goals.

Fluid management of term and preterm infants must also take into account other variables. The amount of insensible water loss is inversely proportional to gestational age. The younger and more physically immature the infant, the higher the skin permeability, the ratio of body surface area to weight, and the metabolic demand. In addition, the use of radiant warmers and phototherapy increases insensible water loss. On the other hand, preservation of body heat with warming devices reduces insensible water loss. The fact that the neonatal kidney is unable to excrete large amounts of excess water or electrolytes must also be considered. As described earlier, the volume of extracellular fluid in a newborn is relatively large. During the first days of life, some of this excess water is excreted. Therefore term newborns have reduced fluid requirements for the first week of life. The daily fluid requirements for a term newborn in the days after birth are estimated to be 70 mL/kg on day 1, 80 mL/kg on day 3, 90 mL/kg on day 5, and 120 mL/kg on day 7. Daily fluid requirements would be slightly higher for preterm infants. Sodium and potassium concentrations are usually kept at 2 to 3 mEq/100 mL and routine serial monitoring of plasma sodium levels are mandatory.

The question of what kind of fluid to administer is at least as important as the amount of fluid. There has been major change in our consideration over the past decade in this regard. Based on the electrolyte composition of either human or cow milk, the original publication from Holliday and Segar defined the daily electrolyte requirements as 2 mEq/100 kcal/day for both potassium and chloride and 3 mEq/100 kcal/day for sodium.[221] This electrolyte administration regimen, along with the "4-2-1" rule, resulted in the frequent administration of excessive quantities of hypotonic fluid solution that, in turn, led to hyponatremia, seizures, cerebral edema, and death. Children are particularly susceptible to cerebral edema with acute hyponatremia. Hospital acquired hyponatremia may occur rapidly in children and may present initially as vomiting and drowsiness.[225] A recent meta-analysis and a large randomized trial convincingly demonstrate that isotonic intravenous maintenance fluids with sodium concentrations similar to that of plasma reduce the risk of hyponatremia when compared with hypotonic intravenous fluids.[226,227] Therefore to maintain homeostasis during the perioperative period, crystalloids should be administered in isotonic compositions.[223,224] Since the composition of the extracellular fluid is comparable between all age groups from newborns to the elderly, the same solutions for infusion can be used in children as for adults (see also Chapter 47). It is, nevertheless, important to note that both hyponatremia and hypernatremia can still develop in children receiving isotonic saline solutions, and routine serial checking of serum sodium concentrations in children undergoing prolonged or extensive interventions is advised.[225]

The use of perioperative dextrose solutions for pediatric populations has undergone important changes over the past decades.[223] Initially, administration of intraoperative dextrose administration was a common practice in pediatric anesthesia care in an attempt to avoid hypoglycemia and its related consequences. It is now, however, well established that the incidence of preoperative hypoglycemia is less than 2.5% and is usually associated with fasting periods well exceeding currently recommended fasting guidelines.[228] On the other hand, the use of 5% dextrose-containing fluid during surgery in pediatric patients has led to hyperglycemia which, in turn, can also lead to increased morbidity and mortality.[228,229] Therefore a growing consensus is that routine administration of dextrose is not necessary in otherwise healthy children receiving anesthesia.[223] The addition of dextrose is important for selected patient populations. Those at highest risk of hypoglycemia include children receiving hyperalimentation as well as those with endocrine/metabolic diseases. In these individuals, adjusting the rate of glucose infusion based on routine blood glucose monitoring is recommended. Neonates and infants also need dextrose supplementation during anesthesia surgery albeit at a lower rate than their normal maintenance requirements.[228,229] The use of 1% to 2.5% dextrose-containing isotonic solutions for intraoperative maintenance in neonates and infants appears to be the best option while serial blood glucose measurements are needed to maintain blood glucose levels in the optimal range.[224,229]

In the absence of well-controlled studies with clearly defined endpoints, there is currently no evidence supporting the role of crystalloids versus colloids in perioperative fluid loss replacement and volume expansion in neonatal and pediatric populations.[223,230] Historically, albumin has been considered as the gold standard for maintenance of colloid osmotic pressure in infants and neonates, and is still the most frequently used plasma expander in these populations. Nevertheless, data supporting the continued use of albumin for general fluid resuscitation in children are lacking. Nonprotein synthetic colloids such as hydroxyethyl starch (HES), gelatin, and dextrans have also been used as plasma expanders in children. While a prospective observational drug safety trial using a third-generation HES revealed no serious adverse drug reactions, such as anaphylaxis, renal failure, or clotting disorder in children with normal renal and clotting function, further studies are needed before presuming safety in patients with renal failure or those at increased risk of bleeding.[223,231] Both the efficacy, in terms of intravascular volume expansion, and the safety profile of HES has been reported comparable to albumin in the setting of pediatric cardiac surgery.[232] Gelatins are polypeptides produced by degradation of bovine collagen. Although the initial formulations of this product induced a high incidence of hypersensitivity reactions, a more recent trial was unable to show evidence of any short- or long-term adverse effects.[233,234] Dextrans are water-soluble glucose polymers. Although these molecules have excellent colloid oncotic powers, they probably should not be used because of their negative coagulation effects and high anaphylactic potential.[223]

Transfusion guidelines for nonneonatal pediatric patients are similar to those for adults.[235] Some precautions, however, should be considered, especially in case of massive transfusion. When caring for children, the emphasis should be on blood volume and percentage loss of blood volume, rather than specific units of blood, since a unit of blood may constitute several blood volumes in a preterm infant, but only a fraction of the blood volume of a robust teenager. These considerations govern the calculation of the maximal allowable blood loss (MABL) resulting in an acceptable hematocrit. MABL takes into account the effect of patient age, weight, and starting hematocrit on blood volume. In general, blood volume is approximately 100 to 120 mL/kg for a preterm infant, 90 mL/kg for a full-term infant, 70 to 80 mL/kg for a child 3 to 12 months old, and 70 mL/kg for a child older than 1 year of age. These volumes are merely estimates of blood volume. The individual child's blood volume is calculated by simple proportion by multiplying the child's weight by the estimated blood volume (EBV) per kilogram. Although several formulas are available, a simple relationship is easiest to remember:

$$\text{MABL} = \frac{\text{EBV} \times (\text{Starting hematocrit} - \text{Target hematocrit})}{\text{Starting hematocrit}}$$

Thus if a 3-year-old child weighs 15 kg and has a starting hematocrit of 38% and if clinical judgment estimates the desired postoperative hematocrit to be 25%, then the calculation would be as follows:

$$\text{MABL} = [(15 \times 70) \times (38 - 25)]/38 = 360 \text{ mL}$$

The MABL would be replaced with 3 mL of lactated Ringer solution per milliliter of blood loss; that is, 3 mL of lactated Ringer solution times the 360 mL of blood loss equals approximately 1080 mL of lactated Ringer solution. If blood loss is less than or equal to the MABL and no further significant blood loss occurs or is anticipated in the postoperative period, then there is no need for transfusion of packed red blood cells (PRBCs). If, however, significant postoperative bleeding occurs or is anticipated, then a discussion with the surgeon can be very helpful in defining and preparing for the potential transfusion needs. Normally, a child who has had adequate replacement of intravascular volume deficits will tolerate anemia very well. In most cases, there is sufficient time to make the decision to transfuse by observing postoperative urinary output, heart rate, respiratory rate, and overall cardiovascular stability. Unfortunately, no one formula permits a definitive decision. The development of lactic acidosis is a late sign of inadequate oxygen-carrying capacity.

If the child has reached the MABL and significantly more blood loss is expected during surgery, then the child should receive PRBCs in sufficient quantity to maintain the hematocrit in the 20% to 25% range. The entire loss of red cell mass should not be replaced unless clinically indicated if these additional PRBCs would expose the child to additional units of blood products. Hematocrit values in the low 20% range are generally well tolerated by most children, the exception being preterm infants, term newborns, and children with cyanotic congenital heart disease or those with respiratory failure in need of high oxygen-carrying capacity. Older children with a history of sickle cell disease may require preoperative transfusion and should be managed in conjunction with their attending hematologist.

The indications and contraindications for the transfusion of fresh frozen plasma (FFP) are essentially the same for children as for adults. FFP is administered to replenish clotting factors lost during massive blood transfusion (usually defined as blood loss exceeding one blood volume), for disseminated intravascular coagulopathy, or for congenital clotting factor deficit. The anesthesiologist initiates and guides therapy with FFP during massive blood loss, whereas the hematologist's advice is sought when either of the other two conditions exists.

Children with known clotting factor deficits, such as those with massive thermal injury or coagulopathy, may require transfusion of FFP before blood loss exceeds 1 blood volume. In contrast, healthy children who do not have coagulation factor deficits at the beginning of surgery do not need FFP until blood loss exceeds 1 blood volume.[236,237] Despite the loss of 1 blood volume, prolongation of the prothrombin time (PT) and the partial thromboplastin time (PTT) will only be minor. This generalization applies to children given PRBCs; children given whole blood will not need FFP, even when blood loss exceeds several blood volumes.

No studies in children have definitively defined values of PT and PTT that are associated with pathologic bleeding for which FFP should be administered. Usually an international normalized ratio (INR) < 2 does not warrant correction. In general, if the clotting factor deficit is associated with abnormal oozing, then a PT exceeding 15 seconds (INR > 1.4) or a PTT greater than 60 seconds (>1.5 times baseline) warrants close observation. If these abnormalities exist but there is limited bleeding in the surgical field, it seems appropriate to observe the child and withhold the transfusion of FFP.

The volume of FFP required to correct prolongation of the PT and PTT values depends on the severity of the clotting factor deficit and the presence or absence of consumptive coagulopathy. In general, FFP therapy may require replacement of 30% or more of the child's blood volume. Transfusion of FFP at rates exceeding 1 mL/kg/min is sometimes followed by severe ionized hypocalcemia and cardiac depression with hypotension, especially if FFP is administered during anesthesia with a potent inhaled anesthetic (Fig. 77.14).[238,239] Therefore exogenous calcium chloride (2.5-5 mg/kg) or calcium gluconate (7.5-15 mg/kg) should be administered, preferably through a separate IV, during rapid transfusion of FFP.[240] Ionized hypocalcemia occurs very frequently in neonates given FFP, possibly because of their decreased ability to mobilize calcium and metabolize citrate. Children undergoing liver transplantation or those with compromised hepatic function or perfusion may also be at increased risk because of a decreased ability to metabolize citrate.

Massive blood transfusion (MBT) in children has been recently defined as transfusion of greater than 50% of total blood volume (TBV) in 3 hours, transfusion of greater than 100% of TBV in 24 hours, or transfusion support to replace ongoing blood loss of greater than 10% of TBV per minute.[241] The management of massive transfusion requires that circulating blood volume is restored and components are given such that hemostasis is maintained or returned to normal.[242,243] A major concept in hemostatic resuscitation is the construction of a balanced transfusion strategy delivering PRBCs, FFP, platelets, coagulation factors, and antifibrinolytics. Adult MBT strategies suggest a PRBC:FFP:platelet ratio of 1:1:1 with early consideration of fibrinogen replacement and the potential use of tranexamic acid. Laboratory evaluation of massive bleeding in pediatric patients is challenging and acute management cannot rely on waiting for the results of these relatively time-consuming examinations. Thromboelastometry and rotational thromboelastometry can be useful monitoring methods, providing more timely assessment than standard laboratory investigations during MBT. Once bleeding has been controlled, appropriate targets after massive transfusion are suggested as Hb 80 g/L, fibrinogen greater than 1 g/L, PT ratio greater than 1.5, platelet count greater than 75 × 109/L (100 × 109/L in traumatic head injury).[243] Permissive hypotension during MBT is an often used strategy in adult trauma setting until definite management of bleeding can be achieved. This approach may not be an appropriate strategy in pediatric populations since children compensate for blood loss with minimal change in vital signs until significant compromise. Complications of MBT are similar to those in adults.[241]

A fluid and blood warmer is essential for any child who might require rapid correction of intravascular volume. Using such devices for maintenance intravenous fluid therapy, however, provides no benefit because the rate of infusion is so slow that the intravenous fluid returns to room temperature between the times that it exits the warmer and enters the child. Administration of large volumes of blood products also requires adequate vascular access. During pediatric trauma, when massive hemorrhage is suspected, if no intravenous access is established after 90 seconds or two attempts, intraosseous access should be utilized.[243] The anesthesiologist should be familiar with the maximal flow rates that can be delivered via intravenous and intraosseous cannulas of different sizes (Table 77.7).[244]

Regional Anesthesia and Analgesia

Most regional anesthesia techniques used in adults can be safely administered to children as long as strict attention is paid to the dose of the local anesthetic, the dose of

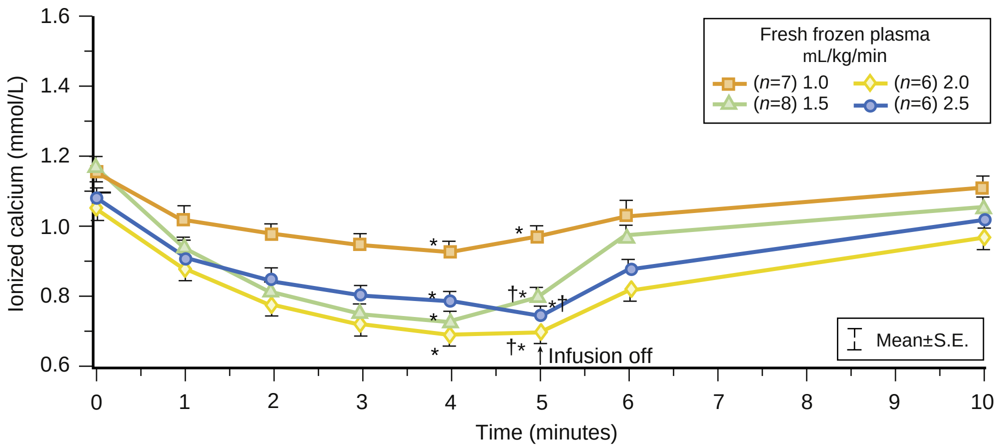

Fig. 77.14 Ionized hypocalcemia always accompanies the administration of citrated blood products (e.g., fresh frozen plasma, citrated whole blood). Fresh frozen plasma has the highest concentration of citrate per unit volume of any blood product and is the most likely to cause ionized hypocalcemia during rapid infusion. Studies in children with thermal injuries suggest that rates exceeding 1 mL/kg/min produce severe ionized hypocalcemia. If no further citrated blood products are administered, then this abnormality corrects itself because of metabolism of the citrate. However, children with impaired hepatic blood flow—infants, patients undergoing liver transplantation, patients with trauma—may need exogenous calcium therapy. **$*P$, <.001; $^{\dagger}P$, <.0021 versus baseline; *S.E.*, standard error.** (From Coté CJ, Drop LJ, Hoaglin DC, et al. Ionized hypocalcemia after fresh frozen plasma administration to thermally injured children: effects of infusion rate, duration, and treatment with calcium chloride. *Anesth Analg.* 1988;67:152–160. epinephrine, and the use of proper equipment. Perhaps the greatest advance in regional pediatric anesthesia has been the development of methods producing postoperative analgesia. Caudal anesthesia, caudal opioids, regional blocks, and child-parent-nurse–controlled analgesia have all been accepted by anesthesiologists and children. Recent advances in ultrasound equipment and techniques have further improved the accuracy of nerve blocks and reduced the dose of drug needed to provide a successful block.

Regional nerve blocks and direct local infiltration of surgical wounds with long-acting local anesthetics are simple yet very effective and safe methods of providing pain relief for all children.[245,246] This practice has been especially helpful in the outpatient population; parents are encouraged to start analgesics when they observe their child becoming irritable but before the complete dissipation of the block. This approach usually provides a smooth transition from general anesthesia and a pain-free child.

Important Pediatric Anesthesia Scenarios

Some patient groups or surgical procedures in children require particular attention when determining optimal anesthesia management.

NEONATAL ANESTHESIA

The neonate has unique requirements for equipment, fluid and drug therapy, anesthetic dosage, and environmental control. Children younger than 1 year of age have a more frequent incidence of complications than older children.[55,247-251] These complications primarily relate to oxygenation, ventilation, airway management, and response to anesthetic medications. An understanding of the basic differences in physiology and pharmacology, and an understanding of the common comorbidities and the underlying pathologic surgical problem is essential for the development of a safe anesthesia plan. Neonates generally have limited cardiovascular and respiratory reserve resulting in a narrow margin for error and the need for meticulous attention to details in all aspects of anesthesia care. Neonates are more likely to have a sudden deterioration in function and thus require careful monitoring and being prepared for rapid and appropriate interventions. Neonates may also have a transitional circulation or undiagnosed congenital malformations or genetic conditions that may become apparent during anesthesia.

As is true for other patient populations, when anesthesiologists are to deliver optimal neonatal anesthesia care, they must always ensure there is thorough preoperative preparation, appropriate monitoring, the proper size and variety of equipment available, and obtain the most intense level of support, both in the operating room and in the ICU. If the anesthesiologist only occasionally cares for infants, then the likelihood of a problem (often unanticipated) dramatically increases. As one example, when caring for the neonate, access to the child may be difficult after the patient is positioned for the surgical procedure, so it is critical that when managing these patients, the airway, intravenous access, and all monitoring should be checked and secure before surgery starts.

The anesthesiologist must devote particular care to the calculation of drug dose and preparation of drugs. Careful attention to the administration of all medications is essential. Prevention of paradoxical air emboli is critical for the pediatric patient. A volume of air that is clinically unimportant in an adult may prove catastrophic in an infant. To reduce the risk of air emboli requires that all air be vented from intravenous devices and syringes before use; each intravenous injection port is aspirated to remove air trapped at these junctions, and some drug is ejected before intravenous administration to clear air from the dead space of the needle. Intravenous fluids should be administered with volume-limiting devices; infusion pumps are particularly helpful in preventing over administration of intravenous fluids. The composition and infusion rate of flush solutions should be noted and calculated into maintenance fluid therapy. In neonates and small infants, a basal infusion rate of balanced salt solution with a pump is most useful, with other fluid or blood product boluses given via piggyback or a three-way stopcock.

Every effort must be made to maintain the infant's temperature to minimize thermal stress. The surgical environment should be warmed and exposure of the neonate kept to a minimum. Forced air warming is particularly useful for maintaining temperature. Fluids should be warmed, and heated mattresses and overhead radiant heaters may also be used.

Monitoring expired concentrations of carbon dioxide can be less accurate in small infants, but is still extremely useful for diagnosing changes over time and for issues such as bronchospasm, a kinked endotracheal tube, or endobronchial intubation. Transcutaneous carbon dioxide monitoring may also be used, although it requires careful calibration and management. Hypocarbia should be avoided due to the risk of cerebral vasoconstriction.

Pulse oximetry is mandatory to detect hypoxia, and also helps avoid hyperoxia. The optimal oxygen saturation for neonates is controversial. High oxygen saturations in premature infants increase the risk of retinopathy of prematurity; however some randomized trials have found that aiming for low (85%-89%) saturations in extremely preterm infants may increase the risk of other neurologic morbidity.[252] During stable situations it is reasonable to aim for an oxygen saturation between 93% and 95% in preterm infants. However, because these infants have the highest oxygen consumption, oxygen saturation in the 93% to 95% range can change to severe hypoxemia within seconds. When managing such a delicate balance and in view of the slight inaccuracies of these monitors, the anesthesiologist must be extremely vigilant and prepared to respond rapidly to changes in oxygen saturation.

The newborn goes through a transitional circulation and it takes some days for the pulmonary circulation to adjust. Hypoxia or acidosis in the newborn can lead to significant pulmonary vasoconstriction and resultant pulmonary hypertension. This may lead to right to left shunting, exacerbating arterial hypoxia and thus leading to a vicious cycle of worsening pulmonary hypertension, acidosis, hypoxia, and eventual cardiovascular collapse.

The neonatal lung is fragile and particularly prone to injury from excessive tidal volumes. In contrast, careful attention to ventilation is required to maintain functional residual capacity and avoid atelectasis. Positive end expiratory pressures should be used. Even brief disconnection of the airway circuit or mechanical ventilator can lead to significant alveolar collapse and should thus be avoided if possible. In the operating room neonates should only be anesthetized with ventilators that are designed to include neonatal use, and it is optimal to have monitoring equipment that can accurately measure tidal volumes in a neonate. It is also increasingly recognized that intubated neonates should be transferred to and from the operating room with appropriate neonatal transport ventilator equipment rather than simply a bag and t-piece. For some critically ill children, it may be safer to perform the surgery in the neonatal intensive care unit (NICU) using NICU ventilators rather than transfer the child to the operating room. Transferring a child that is on an oscillator is particularly challenging. In these cases, however, the NICU staff and surgeons must be prepared to perform the procedure, have all necessary equipment and a process to ensure sterility, and a safe environment for the procedure.

The optimal blood pressure during neonatal anesthesia is unknown. Traditionally an acceptable mean arterial pressure in mm Hg was judged to be roughly the same as the postmenstrual age of the child in weeks; however there is little if any evidence to support this. Recent studies have suggested that the neonatal brain may be particularly susceptible to hypotension.[253]

Little doubt exists that neonates, even extremely preterm infants, are capable of feeling pain and will respond to painful stimuli; indeed preterm infants may be even more sensitive to painful stimuli.[254] Neonates cannot form explicit memories, but there is evidence for implicit memory formation. The differentiation between conscious and unconscious can also be problematic in neonates. No child should be denied analgesia or anesthesia because of size or age. However, what exactly constitutes a state of adequate anesthesia in the neonate is unclear.[255,256] Similarly, difficulty in measuring appropriate endpoints of adequate anesthesia makes it very difficult to determine the optimal dose of anesthetic agents.

Propofol and inhaled anesthetics can result in profound cardiovascular depression in the neonate. In contrast, the synthetic opioids (e.g., fentanyl, sufentanil, alfentanil, remifentanil) are usually well tolerated, even in critically ill infants. When used, these potent opioids must be carefully titrated to a defined response. Anesthesiologists must be particularly cautious about opioid-induced bradycardia and its consequences on cardiac output. Low concentrations of potent inhaled anesthetics can be used with opioids to provide a means of controlling hemodynamic responses without significantly depressing the myocardium. The relative merits of one anesthetic technique over another are not well defined.

Regional anesthesia can be highly effective in neonates. Caudal and spinal anesthesia are relatively straightforward; however the safe placement of a lumbar or thoracic epidural block requires considerable skill. Epidural local anesthetic infusions can result in systemic toxicity due to immature metabolism.

ANESTHESIA FOR SPECIFIC NEONATAL SURGICAL PROCEDURES

Meningomyelocele

Meningomyelocele, the hernial protrusion of a part of the meninges and spinal cord through a defect in the vertebral column, is becoming less common in developed countries due to improvements in maternal folic acid intake and antenatal screening. The following should be considered in addition to the usual concerns for the management of neonates: (1) special positioning for tracheal intubation (i.e., the defect is placed on a "doughnut" and towels are placed under the head); (2) possibility of underestimating fluid and blood loss; (3) high association of meningomyelocele with hydrocephalus; (4) possibility of cranial nerve (vocal cord) palsy, resulting in inspiratory stridor; and (5) potential for brainstem herniation. The anesthesiologist must establish adequate intravenous access to replace all fluid deficits, including loss from the defect (usually with normal saline), and ensure that cross-matched blood is available (especially if rotational skin flaps are planned). Latex allergy precautions should be used with these children for their first and all subsequent anesthetics.

Omphalocele and Gastroschisis

Omphalocele and gastroschisis are major defects in the closure of the abdominal wall that result in exposure of viscera that are either covered (omphalocele) or not covered (gastroschisis) by peritoneum (Fig. 77.15; Table 77.8). The major anesthesia-related problems with these defects include the following: (1) severe dehydration and potential massive fluid loss from the exposed visceral surfaces and due to partial bowel obstruction; (2) heat loss;

(3) raised abdominal pressure with closure; and (4) high association of these conditions with prematurity and other congenital defects, including cardiac abnormalities (with omphalocele, ~20%). These children must have an adequate preoperative work-up that includes an echocardiogram to assess both anatomy and myocardial function. Postoperative ventilation is usually required for these patients as a result of a tight abdominal wall closure. In some cases, a staged approach is needed to complete the repair.

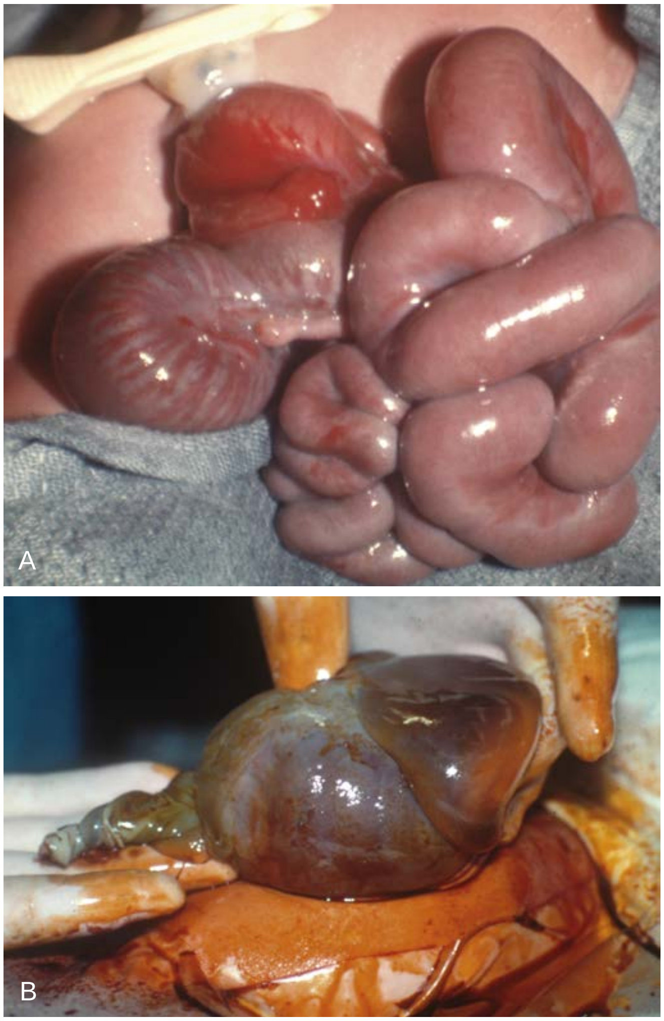

Fig. 77.15 (A) Gastroschisis malformation. The viscera have herniated outside the peritoneum. (B) Omphalocele malformation. The viscera are still covered by peritoneum.

Infants with omphalocele or gastroschisis require careful management preoperatively to minimize the likelihood of infection or compromise of bowel function. For all children, adequate fluid resuscitation should be provided and electrolyte imbalances corrected prior to surgery. Adequate intravenous access is essential. Invasive monitoring is occasionally necessary, particularly if the child has an associated cardiac defect. The liberal use of muscle relaxants provides optimal surgical conditions for closure of the defect. Hypotension during closure may occur due to tension on the liver or caval compression. Similarly raised abdominal pressure during closure may impede adequate ventilation. Postoperative ventilation may be necessary until the abdominal wall has had time to stretch to accommodate the viscera. It should be noted that increased abdominal pressure after a tight closure (abdominal compartment syndrome) may compromise hepatic and renal function and significantly alter drug metabolism. Staged closure with a premade spring-loaded silastic silo is being used with increasing frequency, thus minimizing repeat trips to the operating room. A small percentage of children with omphalocele will also have Beckwith-Wiedemann syndrome, a condition characterized by profound hypoglycemia, hyperviscosity syndrome, congenital heart disease, and associated visceromegaly.

Tracheoesophageal Fistula

A tracheoesophageal fistula can have five or more configurations, most of which are diagnosed after an inability to swallow because of an associated esophageal atresia (the esophagus ends in a blind pouch). In these cases the characteristic diagnostic test is an inability to pass a suction catheter into the stomach. Neonates may have aspiration pneumonitis from a distal fistula connecting the stomach to the trachea through the esophagus or from a proximal connection of the esophagus with the trachea. Neonates with the rarer H-type fistulae have a fistula between esophagus and trachea; however the esophagus is patent with no atresia. These children present later, typically with respiratory distress and chest infections.

The tracheoesophageal fistula may be part of a larger constellation of anomalies known as the VATER association (**V**,

TABLE 77.8 Comparison of Gastroschisis and Omphalocele Malformations

	Gastroschisis	Omphalocele
Pathophysiologic characteristics	Occlusion of the omphalomesenteric artery	Failure of gut migration from the yolk sac into the abdomen
Incidence	~1 in 15,000 births	~1 in 6000 births
Incidence of associated anomalies	~10%-15%	~40%-60%
Location of defect	Periumbilical	Within the umbilical cord
Problems associated with defect	Inflammation of exposed gut Edema Dilated and foreshortened gut (chemical peritonitis)	Congenital heart disease (~20%) Exstrophy of the bladder Beckwith-Wiedemann syndrome (macroglossia, gigantism, hypoglycemia, hyperviscosity)

From Coté CJ, Lerman J, Anderson, BA, eds. *A Practice of Anesthesia for Infants and Children*. 5th ed. Philadelphia: Saunders; 2013.

vertebral; **A**, anal; **TE**, tracheoesophageal; **R**, renal) or the VACTERL association (VATER and **C**, cardiac; and **L**, limb). Any child with a tracheoesophageal fistula or esophageal atresia should be suspected of having the other anomalies. An echocardiogram to examine for a right-sided aortic arch and the presence of congenital heart disease should be performed before anesthesia.[257] Abdominal ultrasound should also be performed to detect major renal abnormalities.

The major anesthetic issues include: (1) already compromised respiratory function due to aspiration pneumonia; (2) overdistention of the stomach from entry of air directly into the stomach through the fistula, particularly after administration of positive pressure ventilation by mask; (3) inability to ventilate the child's lungs because of the large size of the fistula; (4) problems associated with other anomalies, particularly a patent ductus arteriosus and other forms of congenital heart disease.[258] Prior to anesthesia, the infant's feedings should be withheld, a catheter placed in the esophagus to drain saliva, and the infant placed prone in a head-up position. Anesthesia evaluation centers on the pulmonary and cardiovascular systems.

A major aim of anesthesia is to ensure adequate ventilation despite the presence of the fistula. Since positive pressure ventilation may inflate the stomach through the fistula and cause distension of the stomach, it should be avoided until an endotracheal tube is placed distal to the fistula and/or the fistula is occluded or ligated. The risk of abdominal distension and hypoventilation is greatest when the fistula is large or the lung compliance is poor. The distended stomach will further compromise ventilation of the lungs, exacerbating the situation. Several different strategies for anesthesia have been described.[259] Usually an inhalational induction is preferred and spontaneous ventilation is maintained until the fistula is ligated. This is not always possible. Coordination with the surgeon is critical to defining the optimal way to ensure adequate ventilation until the fistula is occluded. Bronchoscopy is usually performed after induction to assess the size and location of the fistula. At bronchoscopy a Fogarty catheter or similar device may be placed directly in the fistula to occlude it. The endotracheal tube is ideally placed in the trachea distal to the origin of the fistula. This may be done blindly by advancing the tube into a main bronchus and then carefully pulling it back until equal air entry is heard. The endotracheal tube may be inadvertently placed into the fistula resulting in rapid gastric distension and arterial oxygen desaturation. If this occurs the tube should be withdrawn. Urgent transcutaneous gastric decompression may be needed or intraabdominal clamping of the distal esophagus through an abdominal incision.

Most repairs are now done thoracoscopically. Invasive blood pressure monitoring is recommended since intraoperative arterial desaturation or hypotension may occur with manipulation of mediastinal structures. A preductal and postductal pulse oximeter can be useful in diagnosing an intracardiac shunting. Some surgeons prefer that the infant remain intubated postoperatively, whereas others prefer an attempt at extubation of the trachea. Postoperative pain may be managed with a local anesthetic infusion, or intermittent bolus, via a caudal catheter threaded up to the thoracic level, or with a paravertebral catheter placed by the surgeon.

Congenital Diaphragmatic Hernia

A congenital diaphragmatic hernia (CDH) consists of herniation of the abdominal viscera through a defect in the diaphragm, most commonly the foramen of Bochdalek on the left side. Many of the abdominal viscera, including the liver and spleen, may be above the diaphragm. Approximately half the cases are diagnosed antenatally. More than half of CDH cases are associated with other congenital anomalies and therefore a full evaluation of all systems should be performed prior to surgery. The primary concern with respect to anesthesia management is pulmonary hypoplasia and associated pulmonary hypertension. It is important to note that surgery does not directly correct the pulmonary hypertension and respiratory status may acutely deteriorate postsurgery. Thus surgery should not be rushed, but planned for when the child is in optimal condition. Preoperatively extracorporeal membrane oxygenation (ECMO) and the use of nitric oxide have become important aspects to the management of CDH; however there is mixed evidence that they improve outcome and ECMO should only be used in the most severe cases.[260,261] Sildenafil and prostacyclin may also be used to manage pulmonary hypertension. High-frequency oscillatory ventilation is often required and permissive ventilation is also advocated (limiting peak inspiratory pressures and PEEP with resultant permissive hypercapnia).[262]

The surgery may be open via a subcostal incision or done thoracoscopically. It is often performed in the ICU to avoid transferring the child to the operating room. Anesthetic management of children with a diaphragmatic hernia includes the following: (1) preventing any exacerbation of pulmonary hypertension through avoiding hypoxemia and excessive hypercapnia, and blunting the stress response (e.g., with high-dose fentanyl, 25 µg/kg or more); (2) avoiding bag and mask ventilation prior to intubation of the trachea as this may result in gastric distension within the chest; (3) avoiding nitrous oxide to prevent any risk of expansion of viscera in the chest; (4) awareness of the risk for the development of barotrauma-induced pneumothorax on the ipsilateral or contralateral side; and (5) meticulous fluid management and inotopic support of the circulation if needed. Other methods to address the CDH have been attempted, including fetoscopic endoluminal tracheal occlusion. This approach, while successful in selected cases, is still regarded as an experimental approach to managing CDH.[263]

ANESTHESIA FOR SPECIFIC SURGICAL PROCEDURES IN INFANTS

Pyloric Stenosis

Pyloric stenosis is diagnosed from 1 week to 3 months of life, typically after persistent projectile vomiting. The child may be severely dehydrated with a profound hypochloremic, hypokalemic, metabolic alkalosis. This procedure is never a surgical emergency. Children should be carefully evaluated, and any dehydration or metabolic imbalance should be corrected before surgery. The metabolic imbalance and dehydration can be corrected slowly, provided there is no cardiovascular instability and hypovolemic shock. A persistent alkalosis increases the risk of postoperative apnea and it should be noted that correction of the CSF pH may lag several hours behind plasma pH correction.

Increasingly the myotomy is performed laparoscopically. Nasogastric tubes are not always used preoperatively as they may worsen the electrolyte imbalance. Aspiration of gastric contents during induction is a primary concern. Even if the child arrives with a nasogastric tube in place the stomach should still be immediately suctioned with a wide-bore vented catheter in the supine and the right and left lateral positions immediately before induction of anesthesia. This suctioning technique will generally remove 98% of the gastric contents.[264] A wide variety of techniques have been described for the induction of children with pyloric stenosis. Awake-intubation has been frequently used; however this approach is becoming less common. One study demonstrated fewer attempts and one half the time for successful intubation of the trachea when a muscle relaxant was used.[265] The classically described rapid sequence technique (preoxygenation, cricoid pressure, and avoiding mask ventilation) may not be appropriate for an infant with pyloric stenosis. Cricoid pressure can easily distort the anatomy making laryngoscopy difficult. If it is applied and there is no clear view of the larynx then the pressure should be relaxed. It may also not be appropriate to avoid mask ventilation. Infants rapidly desaturate with apnea so it is often necessary to gently ventilate the child with 100% oxygen prior to laryngoscopy to avoid hypoxemia and bradycardia. A variety of different intravenous anesthetic agents and neuromuscular blocking agents have been described in this situation. Atropine (0.02 mg/kg) should be given to prevent bradycardia if succinylcholine (2 mg/kg) is used. Postoperative analgesia is generally provided by local infiltration of the skin incision and acetaminophen. Rectus sheaf and transversus abdominis plane blocks have also been described in this setting.

Reports of apnea events after pyloromyotomy have been reported.[266] Children who undergo this procedure should be closely monitored with both apnea monitors and pulse oximetry postoperatively.

Infant Inguinal Hernia Repair

Inguinal hernia repair is one of the most common surgeries performed in infants. Inguinal hernia is often bilateral and is more common in males and in ex-premature infants. The optimal timing of surgery is controversial. Waiting until the child is older may reduce anesthesia risk; however, an unrepaired asymptomatic hernia is still at risk of incarceration, which may be a life-threatening complication. The repair may be performed laparoscopically or open. Anesthesia may be with an awake-regional technique or general anesthesia. The awake-regional technique is usually with a spinal anesthetic. Awake-caudal anesthesia has been described but usually requires substantial additional sedation. Spinal anesthesia has fewer complications in PACU and shorter PACU stay but fails in approximately 10% to 20% of cases.[267-269] This may be due to inability to find the subarachnoid space or the child failing to adequately settle even with an effective block. The spinal anesthetic usually provides 60 to 90 minutes of anesthesia and thus may not be appropriate for hernia repair that is anticipated to be complex. The spinal block may be augmented with a caudal local anesthetic block. General anesthesia for inguinal hernia repair may be with an endotracheal tube or LMA. A caudal local anesthetic block, ilioinguinal block, or local infiltration of local anesthetic by the surgeon can all provide adequate analgesia and obviate the need for opioids.

The major anesthesia concern around infant inguinal hernia repair is the risk of postoperative apnea. The majority of infants who develop postanesthesia apnea are former preterm infants (gestational age <37 weeks) and younger than 44 weeks postmenstrual age (PMA); however, apnea can occur at up to 60 weeks PMA.[270] Studies evaluating postoperative apnea are difficult to interpret or compare due to widely varying definitions of apnea and methods to detect apnea. In one combined analysis the risk of postoperative apnea increases with lower PMA and lower gestational age.[271] Anemia (hematocrit <30%) was also found to be an independent risk factor associated with apnea in former preterm infants. Apnea still occurs even with sevoflurane or desflurane anesthesia; therefore the newer volatile anesthetics have not eliminated this concern.[272] The risk of early apnea is less with awake-regional anesthesia; however, the risk of late apnea may be similar.[267,273] There is also some evidence that those who required sedation with spinal anesthesia have increased risk of apnea compared to those who had no sedation.[274]

A Cochrane review found some evidence that prophylactic methylxanthine (caffeine) reduces the risk of postoperative apnea; however, it was cautious about recommendations for its routine use.[275] Caffeine may not reduce the risk of late apnea. Recommendations vary, but in general, all former preterm infants younger than 56 to 60 weeks' PMA should be admitted after inguinal hernia repair for apnea monitoring.[271,276,277] The risk for term infants is poorly defined; however, apnea is still considered a risk up to 44 weeks' PMA.

Cleft Lip and Palate

Cleft lip and palate are relatively common congenital malformations. Approximately one third are associated with a wide range of other syndromes so careful and thorough preoperative assessment is required. Cleft lip is usually repaired at 3 to 6 months of age whereas the palate is repaired at 9 to 12 months of age. Difficult airway may occur but is unusual unless there is also retrognathia. In children with large or bilateral clefts, the tongue may impinge in the cleft obstructing the airway, or the laryngoscope blade may fall into the cleft. Correction of the lip is usually a straightforward procedure. Cleft palate repair may be complicated by postoperative obstruction. The child should be extubated awake. Postoperative analgesia is based on regular acetaminophen and the judicious use of opioids. Infraorbital nerve blocks also provide effective analgesia for cleft lip repair.[278]

ANESTHESIA FOR SPECIFIC PROCEDURES AND CONDITIONS IN OLDER CHILDREN

Anterior Mediastinal Mass

In children, anterior mediastinal masses may be due to a range of pathology with lymphoma being the most common. They may cause airway and/or vascular compression. This may be asymptomatic or result in dyspnea, orthopnea, pain, cough, or superior vena cava syndrome. These children frequently present for a biopsy of the lesion or other lymph node which, for accurate diagnosis and appropriate management, must be obtained prior to any chemotherapy or radiotherapy. The major anesthesia concern is profound cardiorespiratory collapse and death on induction of anesthesia. Such collapse can occur in a child that is asymptomatic preoperatively. The exact etiology of this collapse is uncertain, but probably relates to increasing compression of major vessels, heart, and/or the airway. The collapse may be triggered by paralysis or positive pressure ventilation. As a result, some pediatric anesthesiologists advocate avoiding neuromuscular blocking agents and maintaining spontaneous respiration. Preoperative assessment should include a careful history and examination to determine if positioning has any impact on symptoms and chest computed tomography (CT) and echocardiography. Occlusion of greater than 50% of the airway on CT is associated with increased risk of significant obstruction under anesthesia. Echocardiography can be helpful to determine if positioning might have any impact on compression of vessels and cardiac function. If collapse does occur on induction, changing the child's position to lateral or prone may be life saving. In severe cases, every effort should be made to obtain the biopsy without general anesthesia so that further management options can be determined.

Inhaled Foreign Body

Inhalation of foreign bodies is a major source of morbidity and mortally in young children, occurring most frequently in children ages 1 to 2 years. The airway obstruction may be acute, causing significant respiratory distress and require urgent management; however, often the diagnosis is delayed. Partial obstruction may be undiagnosed for days or even weeks. The acute choking episode may not have been witnessed and the child may present late with signs of pneumonia. The urgency of removal depends on the degree of respiratory symptoms and the likely location of the obstruction. Ideally the child should be fasting. Several anesthetic techniques have been described. Clear, effective, and ongoing communication with the surgeon before and throughout the procedure is paramount. Often anticholinergic agents are given prior to induction to reduce secretions and steroids given to reduce airway swelling. Ideally, spontaneous ventilation is maintained to reduce the risk of positive ventilation pushing the object further distally, which makes extraction more technically challenging. Once the child is deeply anesthetized, local anesthetic should be directly applied to the glottis and trachea. Anesthesia may be maintained with volatile agents through the bronchoscope or with a propofol infusion. Propofol infusion may provide a more reliable delivery. It also avoids the issue of volatile agent exposure to the surgeon. Remifentanil infusion may also be used to help obtund airway reflexes but should be used judiciously to avoid unwanted apnea. Muscle relaxation may be required in some situations but relaxants should never be given before establishing that positive pressure ventilation is safe.

Tonsillectomy and Obstructive Sleep Apnea

Tonsillectomy and/or adenoidectomy are some of the more common surgical procedures in children. While not performed as often as they were in the past, the most common indications include recurrent infection and airway obstruction, including obstructive sleep apnea. A wide variety of techniques have been described for tonsillectomy/adenoidectomy. For maintenance of anesthesia, inhalational and TIVA can be used. A flexible laryngeal mask airway or a preformed Ring-Adair-Elwyn (RAE) endotracheal tube may be used for the airway. Kinking or displacement of the LMA or RAE tube is not uncommon when the surgeon inserts the mouth gag. Children may be extubated awake or deep. Deep extubation may avoid bleeding associated with coughing during emergence but there is an increased risk of airway obstruction after the airway is removed. If children are extubated deep it is essential that they are subsequently managed in an environment that can rapidly and effectively detect and manage any airway obstruction. Postoperative nausea and vomiting is common after this surgery and prophylactic antiemetics should be used. Dexamethasone is often given to reduce swelling and emesis; however, dexamethasone should never be given if lymphoma is a likely cause of tonsillar hypertrophy as dexamethasone may produce lethal hyperkalemia from tumor lysis. Effective analgesia is a challenge after tonsillectomy/adenoidectomy. Acetaminophen alone is insufficient. Nonsteroidal anti-inflammatory drugs (NSAIDs) are used in many centers; however some surgeons avoid their use due to concerns over bleeding even though there is good evidence that bleeding is not increased.[279] Local anesthetic infiltration to the tonsillar bed may provide some analgesia and some surgeons infiltrate with epinephrine to reduce bleeding. Such infiltration must be done cautiously as injection into the major vessels beneath the tonsillar bed may result in seizures or cerebral infarction. Tonsillectomy is associated with significant pain for up to 10 days or more postoperatively.[280] Opioids are often required for tonsillectomy, both in the immediate recovery and early days after the child goes home. They should be used carefully in the presence of obstructive sleep apnea. Bleeding after tonsillectomy may occur immediately postoperatively or in the early days after discharge. Minor bleeding may be managed conservatively but active ongoing bleeding requires anesthesia for surgical management. Anesthesia for a bleeding tonsil requires consideration of: (1) acute hypovolemia associated with massive blood loss—these children must always be adequately resuscitated before anesthesia; (2) presence of a full stomach—the child may have swallowed a large amount of blood; and (3) a potentially difficult airway management and laryngoscopy due to active bleeding and airway swelling.

Children scheduled for tonsillectomy/adenoidectomy frequently have a degree of obstructive sleep apnea. Obstructive sleep apnea (OSA) is defined as a "disorder of breathing during sleep characterized by prolonged upper airway obstruction and/or intermittent complete obstruction (obstructive apnea) that disrupts normal ventilation during sleep." These children also have an altered response to carbon dioxide.[281] The gold standard to diagnose severity of OSA is the formal polysomnogram.[282] The apnea-hypopnea index (AHI) and the respiratory disturbance index (RDI) are measurements of the presence and severity of OSA syndrome. The AHI is the number of discrete obstructive events per hour while the RDI includes central apnea as well as apnea due to obstruction. OSA is regarded as severe if the AHI is greater than 10 and the oxygen saturation nadir is less than 80%. Most children, however, will have surgery for obstructive symptoms without having had a formal polysomnogram. Thus a variety of other scores based on overnight oximetry, child factors, and degree of symptoms have been developed to assess degree of obstruction and hence perioperative risk.[283]

The main problems that anesthesiologists must consider include when it is safe to send a child with OSA home after tonsillectomy/adenoidectomy and how best to provide postoperative analgesia. There is considerable variation in practice surrounding postoperative management of children with and without OSA. The ASA has published a set of guidelines.[284] Some day-surgery centers routinely send children who do not have OSA home after tonsillectomy; others hold the children for at least 4 hours (the interval during which bleeding or respiratory compromise will most likely occur), and then an additional 7 hours if there have been any obstructive events. Children with known or suspected severe OSA should be monitored overnight. Children with comorbidities such as Down syndrome, or craniofacial abnormalities, younger age (>3 years), or obesity should also be considered for overnight admission and monitoring.

Pain management can be challenging for these patients. Usually opioids are required for analgesia; however some centers avoid opioids and supplement acetaminophen with NSAIDs. If opioids are used, some suggest that children with OSA should have reduced doses. Codeine is no longer recommended for analgesia after tonsillectomy/adenoidectomy as there have been reports of deaths after tonsillectomy related to altered conversion of the prodrug codeine to morphine.[90,285] A small proportion of children have genetically determined rapid conversion to morphine.[286] Thus the combination of OSA-induced opioid sensitivity and rapid metabolism can lead to fatal outcomes. The FDA has issued a warning strongly recommending that codeine not be administered to children for post-tonsillectomy analgesia, particularly to those with obstructive sleep apnea.

Muscle Biopsy

Children may require muscle biopsy to assist the diagnosis of a myopathy or other neurodegenerative condition. There are a broad range of myopathies that present a range of issues for anesthesia (see Chapter 35). These include existing compromised cardiac or respiratory function, developmental delay, poor nutritional status, and risks for malignant hyperthermia, rhabdomyolysis, and propofol infusion syndrome. Thorough preoperative assessment is essential, including an assessment of respiratory and cardiac function.[287] There must also be clear communication with the referring physician to identify and discuss the most likely diagnosis, and which tests will be performed on the biopsy. The optimal anesthetic technique is dependent on knowing this information.[288]

Awake-regional anesthesia would be the ideal option for cooperative older children but is rarely feasible in younger children.[289] When choosing the optimal anesthetic agents, the following patient-related factors should be considered:

- Succinylcholine is contraindicated in children with muscular dystrophy due to risk of acute rhabdomyolysis.
- Halogenated volatile anesthetics have been associated with rhabdomyolysis with muscular dystrophy, particularly Duchenne and Becker muscular dystrophy, younger children, and children with an elevated creatinine kinase.[290,291]
- Some children with mitochondrial disorders may be more susceptible to adverse metabolic and cardiac events after propofol.[292,293] This may be linked to propofol infusion syndrome.

The impact of anesthesia on the biopsy specimen also needs consideration:

- If a contracture test is planned then a "nontriggering" anesthetic is required. Care should also be taken that no local anesthetic contaminates the specimen.
- Some metabolic clinicians prefer propofol to be avoided if a mitochondrial enzyme analysis is planned.

In summary, there is no single, optimal anesthetic for children having the muscle biopsy. The choice of anesthetic agents requires a clear understanding of (1) the likely diagnosis and hence balance of risks, (2) any anesthesia-related requirements stipulated by the laboratory analyzing the sample, and (3) tailoring the plan to the child's particular cardiorespiratory status and ability to tolerate an awake procedure.

Child With Developmental Disability

Children with developmental disability are more likely to require anesthesia for surgery and a range of other procedures. They are however often neglected in terms of systematic research. For example, most studies looking at premedication exclude children with developmental disability, in spite of the fact that they may need it, and benefit from it more than other children.

A key aspect in the perioperative care of these children is to appreciate that they represent a heterogeneous group with a wide range of disabilities and varying clinical needs. These children often have multiple diagnoses and several comorbidities. Even those with a single diagnosis, such as autism spectrum disorder (ASD), may present with a wide range of behavioral issues. No two children with ASD are the same and care must be tailored to each child.[294,295] Another key element is to engage the parents or caregivers early in planning. They are best placed to give advice on what aspects of management will be challenging and what strategies are likely to work best.

Children with ASD often have fixed routines. Similarly children with ASD may find particular actions, environments, noises, or smells distressing. Knowing and accommodating these will reduce distress. Children with ASD also may find communication easier if things are explained with pictures.

Cerebral palsy describes a broad spectrum of movement and posture disorders with varying severity. Anesthesia challenges include poor nutrition, concurrent poor respiratory status, poor cough reflex, reflux of gastric contents, difficulty with positioning, susceptibility to pressure injuries, hypothermia, and difficult venous access.[296,297] Muscle spasm after surgery may result in significant pain. Spasm may be effectively reduced with regional analgesia techniques and/or diazepam. Opioids are often required and must be used carefully to avoid respiratory depression. Titrating analgesia to effect may be difficult in children with cognitive impairment. Often parents or caregivers are the best judges of whether or not their child is in pain.

Acknowledgment

The editors and publisher would like to thank Dr. Charles J. Cote for contributing a chapter on this topic in the prior edition of this work. It has served as the foundation for the current chapter.

Anesthesia for Pediatric Cardiac Surgery

EDMUND H. JOOSTE, KELLY A. MACHOVEC, and WILLIAM J. GREELEY

KEY POINTS

- Organ system maturation, from birth through adolescence, affects physiologic function and therefore anesthetic and surgical management and outcome.
- The understanding of congenital heart disease (CHD) and consequent anesthetic management is based on the pathophysiologic determinants of four categories of defects: shunts, mixing lesions, stenotic lesions, and regurgitant lesions.
- The chronic sequelae of CHD (repaired, palliated, or unrepaired) affect anesthetic management: ventricular failure, residual hemodynamic effects (e.g., valve stenosis), arrhythmias, and pulmonary blood flow changes (e.g., pulmonary artery hypertension).
- Preoperative assessment of cardiac status and planning are the keys to a successful anesthesia outcome.
- Intraoperative transesophageal echocardiography and central nervous system (CNS) monitoring enhance surgical outcome and reduce morbidity.
- The induction technique needs to consider degree of cardiac dysfunction, cardiac defects, level of sedation achieved with premedication, and the presence of an indwelling venous catheter. Other factors to be considered include pulmonary hypertension, electrical rhythm disorders, and other comorbidities.
- The maintenance of anesthesia depends on the age and condition of the patient, the nature of the surgical procedure, the duration of cardiopulmonary bypass (CPB), and the need for postoperative ventilation. It is usually desirable to return the patient to an arousable, sedated state with spontaneous ventilation at the end of the procedure.
- The physiologic effects of CPB on neonates, infants, and children are significantly different from the effects on adults. During CPB, pediatric patients are exposed to biologic extremes not seen in adults, including deep hypothermia (18°C), increased hemodilution, low perfusion pressures, and wide variation in pump flow rates.
- After repair of complex congenital heart defects, separating patients from CPB may be difficult. The causes may be an inadequate surgical result, pulmonary artery hypertension, low systemic vascular resistance, low hemoglobin, and right or left ventricular dysfunction
- The use of modified ultrafiltration (MUF) reverses the deleterious effects of hemodilution and the inflammatory response associated with CPB in children. Furthermore, with MUF perioperative blood loss and blood use are significantly reduced, left ventricular function and systolic blood pressure are improved, oxygen delivery is increased, and pulmonary compliance and brain function are also better.
- Neonates, infants, and children undergoing cardiac surgery with CPB have a more frequent rate of postoperative bleeding than that seen in older patients. This is due to an inflammatory response that a disproportionate exposure to the nonendothelialized extracorporeal circuit produces, the type of surgery performed in neonates and infants that involves more extensive reconstruction and suture lines, the frequent utilization of deep hypothermia or circulatory arrest, a more immature coagulation system in neonates, and an increased bleeding tendency in patients with cyanotic heart disease.
- The management of the postoperative patient warrants an understanding of both normal and abnormal convalescence after anesthesia and cardiac surgery, as it is characterized by continuous physiologic change.
- The care of adults with CHD is a new and expanding field of medicine that requires the skilled management of an experienced multidisciplinary team.
- Additional anesthetic considerations exist in patients with CHD who undergo transplantation, closed heart operations without CPB, cardiac interventional procedures, and noncardiac surgery.

Cardiac surgery is an established and effective treatment for children with congenital heart defects. Early successes in surgical treatment led to a new therapeutic era in the management of congenital heart disease (CHD) and fostered the development of the subspecialties for pediatric cardiology and cardiac surgery and their collaboration. Through this cooperative effort, tremendous progress in medical diagnosis and surgical treatment has been achieved. In turn, these accomplishments gave rise to the development of pediatric cardiac anesthesiologists, individuals who understand the pathophysiology of congenital heart malformations, the diagnostic and surgical procedures used to treat heart disease, and the principles of pediatric and cardiac anesthesia and intensive care medicine. Pediatric cardiac anesthesia continues to evolve as an exciting and technically demanding subspecialty in which anesthetic management is based on physiologic principles.

Cardiovascular surgery and anesthesia in CHD are often performed under unusual physiologic conditions. Rarely in clinical medicine are patients exposed to such biologic extremes as during surgery for CHD. Commonly, patients are cooled to 18°C, are acutely hemodiluted by more than 50% of their extracellular fluid volume, and undergo periods of total circulatory arrest lasting up to 1 hour. Management of patients under these physiologic extremes is a vital function of the pediatric cardiovascular anesthesiologist. As with other areas of medicine, the application and management of technology preceded a comprehensive understanding of its physiologic effects.

Clearly, the perioperative management of these complex cases requires a group of physicians (surgeon, anesthesiologist, cardiologist, critical care specialist), nurses, and perfusionists to work as a team. Although the quality of the surgical repair, the effects of cardiopulmonary bypass (CPB), and postoperative care are the major determinants of outcome, meticulous anesthetic management is also imperative. Ideally, despite the complexity of the cases and the marked physiologic changes attributed to CPB and the surgical procedures, anesthetic care should never contribute substantially to morbidity or mortality.[1] The challenge is to understand the principles underlying the management of patients with CHD and apply them to clinical anesthesia.

Unique Features of Pediatric Cardiac Anesthesia

Pediatric cardiovascular management is unique, with important differences from adult cardiac surgery (Box 78.1). These differences are attributable to normal organ system maturation in the neonate and young infant, differing pathophysiologic conditions in CHD, the diversity of surgical repairs, and the use of specialized CPB techniques such as deep hypothermia, total circulatory arrest, cerebral regional perfusion, and three-region perfusion techniques.

PHYSIOLOGIC CONSIDERATIONS AND MATURATIONAL FEATURES OF THE PEDIATRIC PATIENT

The cardiovascular system changes markedly at birth because of a dramatic alteration in blood flow patterns (Fig. 78.1). During fetal life, blood flow returning to the right atrium (RA) bypasses the unventilated fluid-filled lungs. Blood is then preferentially shunted across the patent foramen ovale into the left atrium (LA) or passes from the right ventricle (RV) across the patent ductus arteriosus (PDA) to the systemic circulation. At birth, physiologic closure of the PDA and of the foramen ovale brings about the normal adult circulatory pattern. The presence of certain congenital heart defects or pulmonary disease can disrupt this normal adaptive process, creating a transitional circulation in which right-to-left shunting persists across the foramen ovale or the PDA. Under such circumstances, the continued presence of a transitional circulation can lead to severe hypoxemia, acidosis, and hemodynamic instability, which are poorly tolerated in the neonate. In contrast, when initially treating some forms of CHD, the prolongation of this transitional circulation is actually beneficial, promoting systemic blood flow or pulmonary blood flow (PBF) and postnatal viability. An example of the latter is pulmonary atresia, in which PBF is supplied via the PDA. In the absence of collateral vessels, closure of the PDA eliminates the principal source of PBF, resulting in hypoxemia and death. In such patients, ductal patency can be maintained with the administration of prostaglandin E1. Importantly, the transitional circulation can be manipulated by pharmacologic and ventilatory strategies, thereby promoting hemodynamic stability.

BOX 78.1 Unique Characteristics of Pediatric Cardiac Anesthesia

Patient

- Normal organ system development and maturational changes of infancy
  - *Cardiovascular:* Blood flow patterns of circulation at birth, myocardial compliance, systemic and pulmonary vasculature, and β-adrenergic receptors
  - *Pulmonary:* Respiratory quotient, closing capacity, chest compliance
  - *Central nervous system:* Brain growth, cerebral blood flow, autonomic regulation
  - *Renal:* Glomerular filtration rate, creatinine clearance
  - *Hepatic:* Liver blood flow, microsomal enzyme activity
- Disease and growth interrelationship
- Effects of systemic disease alter somatic and organ growth
- Compensatory ability of developing organs to recover from injury
- Immunologic immaturity of the infant
- Obligatory miniaturization (i.e., small patient size and body surface area)

Congenital Heart Disease

- Diverse anatomic defects and physiologic changes
- Altered ventricular remodeling owing to myocardial hypertrophy and ischemia
- Chronic sequelae of congenital cardiac disease

Surgical Procedures

- Diversity of operations
- Frequent intracardiac and right ventricular procedures
- Use of deep hypothermia and circulatory arrest during repair
- Trend toward repair in early infancy
- Evolution of surgical techniques to avoid residua and sequelae
- Trend toward wider application of certain operations

Another unique feature of the normal neonatal and infant cardiovascular system is the reduced myocardial reserve in contrast to that in the healthy adult. The newborn left ventricular function is restricted by a reduced number of α-adrenergic receptors, high resting levels of circulating catecholamines, limited recruitable stroke work, an immature calcium transport system, and decreased ventricular compliance.[2] These factors limit contractile reserve with the result of a left ventricle (LV) with a high level of resting tone. Although the resting performance of the neonatal myocardium may be greater than in adults and older children, sensitivity to β-blockade is greater and only modest increases occur in cardiac performance after administration of the β-agonist drugs dobutamine and isoproterenol.[3] Furthermore, the contractile mass of the heart is effectively reduced, resulting in a ventricle with low compliance. Preload augmentation is effective at low filling pressures (1-7 mm Hg). However, when left-sided filling pressures exceed 7 to 10 mm Hg, further increases in left ventricular stroke volume are minimal.[2] As a consequence, neonates are more dependent on heart rate and, to a lesser extent, on preload, to maintain cardiac output at filling pressures of 7 to 10 mm Hg or greater.[4] Additionally, the calcium transport system in the neonatal myocardium is underdeveloped. The neonatal heart therefore depends more on extracellular calcium levels than the adult myocardium,[5,6] and normal or even elevated plasma levels of ionized calcium may be necessary to augment or maintain an effective stroke volume. This is in contrast to adult cardiac patients, in whom calcium use during cardiac surgery has fallen into some disfavor, owing to direct concerns over myocardial ischemia and reperfusion injury.

Another unique feature relates to the pulmonary circulation. The pulmonary circulation undergoes significant changes during the first months of life. In the immediate newborn period, the large decrease in pulmonary vascular resistance (PVR) is due to lung expansion and the vasodilatory effects of a higher PaO_2 than existed in utero. Further decline in PVR throughout the next 2 months of life is attributable to regression of the smooth muscle layer in the pulmonary arterioles. A corresponding decrease in pulmonary artery pressure occurs as PVR declines. Acute physiologic stress in the newborn period, such as hypoxemia or acidosis, may increase pulmonary artery pressure and thus PVR. If the resulting right ventricular hypertension causes reduced right ventricular compliance, right-to-left shunting can occur at the foramen ovale. Once PVR exceeds systemic vascular resistance (SVR), right-to-left shunting develops at the PDA. Either phenomenon will worsen the hypoxemia and eventually limit tissue oxygen (O_2) delivery. In contrast, left-to-right shunts, such as those present with a ventricular septal defect (VSD), increase PBF which over time produces intimal changes in the pulmonary vasculature, delaying regression of medial muscle hypertrophy and producing persistent elevation of PVR.

Size differences between adult and pediatric cardiac patients require different anesthetic techniques and miniaturization. Anatomically, pediatric patients have smaller upper and lower airways, smaller veins and arteries, and decreased body surface area compared to adult patients; these differences have anesthetic implications. Availability of ultrasound has made placement of arterial catheters more expedient, even in the smallest patients, reducing the need for arterial cutdown. Pulmonary artery catheters are used infrequently because of technical difficulties in positioning the tip in the pulmonary artery and because of the fundamental fact that pulmonary flow bears no obligatory relationship to systemic output in children with either intracardiac or extracardiac communications. Transthoracic catheters for pressure monitoring and delivery of vasoactive substances may be placed from the surgical field instead of percutaneous approach via the neck. Adequacy of surgical repair and function is assessed by transesophageal echocardiography (TEE) with Doppler color flow imaging with miniaturized probes.[7,8]

Patient size also influences CPB management. The ratio of pump priming volume to patient blood volume is considerably higher in small children than in adults, resulting in a greater degree of hemodilution. Several studies demonstrated a heightened inflammatory response to CPB in children in contrast to in adults,[9] related to the disproportionate exposure of the child's blood elements to the nonendothelialized surfaces of the pump circuit per body surface area.

In pediatric patients with CHD, the cardiovascular system often represents the sole cause of the medical problem. A special disease and growth interrelationship, unique to growing infants and children, permits developing organs to compensate for and modify existing disease processes. Reparative and recuperative processes in children are greater as a result of this compensatory ability of developing organ systems. Despite adaptation to their cardiovascular pathologic processes CHD pediatric patients do experience detrimental and sometimes permanent effects on somatic growth and on the growth and development of the brain, myocardium, and lung.

The premature infant with CHD deserves special consideration. Premature infants are classified as low birth weight (31-34 weeks, 1-1.5 kg), very low birth weight (26-30 weeks, 600 g-1 kg), and extremely low birth weight (<26 weeks, 400-600 g). Respiratory failure is common and multifactorial. The small airways are prone to obstruction, which results in increased airway resistance and work of breathing with easy fatigability. Lung compliance is reduced because of a deficiency of surfactant, resulting in intrapulmonary shunting and ventilation-perfusion mismatch. Mechanical ventilation prevents alveolar collapse, maintains patency of the airway, and maintains lung volume, preventing hypoxia, but must be used cautiously as premature lungs are susceptible to barotrauma and oxidant injury. Ventilatory strategies for lung protection include reduced peak inspiratory pressures and the lowest inspired oxygen concentration that produces reasonable levels of oxygenation.

Premature infants are also prone to perioperative periods of apnea that may be central in origin or obstructive, either of which can be aggravated by anesthetic drugs. Apnea may also be precipitated by abrupt changes in oxygenation or pulmonary mechanics, brain hemorrhage, and hypothermia. After emergence from anesthesia, sustained apnea may occur and persist for up to 48 hours. Continuous apnea and saturation monitoring with correction of anemia (hematocrit > 30) and intravenous administration of caffeine are therapeutic options. The incidence of postoperative apnea is related to postconceptional and gestational age, the presence of anemia, and the type of surgical procedure.

Cardiac pathophysiology can compound respiratory concerns. The premature heart is a poorly contractile organ with poor diastolic function, and is sensitive to changes in intracellular calcium. Cardiac output depends chiefly on heart rate, with marginal reserve. The premature infant also has a relatively low absolute blood volume and tolerates blood loss poorly. Autoregulation is not well developed, and blood loss compromises cerebral and coronary flow before other manifestations of hypovolemia. However, fluid overload is also not well tolerated. Patency of the ductus arteriosus results in left-to-right shunting and pulmonary overcirculation with heart failure (HF). If uncorrected, this would result in pulmonary hypertension secondary to the development of pulmonary vascular intimal hypertrophy.

Thermoregulation by nonshivering thermogenesis is also poor owing to inadequate stores of brown fat in prematurity. It is critical to maintain normothermia by increasing the operating room temperature, using incubators for transport, warming and humidifying respiratory gases, and warming all intravenous fluids. Glycemic control is difficult, with a tendency to both hypoglycemia and hyperglycemia. Frequent glucose checks are important. Parenteral glucose solutions should be continued in the perioperative period. Premature infants are also prone to retinopathy of prematurity with high inspired O_2 concentrations and intraventricular hemorrhage. Every attempt should be made to avoid hemodynamic perturbances and fluctuation in O_2 saturations. In general, immaturity of organ systems results in both increased drug effect and duration of action, warranting careful titration of drugs.

Premature infants have a twofold increase in cardiovascular malformations compared with term infants.[10] One in six infants with CHD, not including those with PDA or atrial septal defect (ASD), is born prematurely. Some malformations such as tetralogy of Fallot (TOF), pulmonary stenosis, pulmonary atresia with VSD, complete atrioventricular (AV) septal defect, large VSDs in isolation or associated with coarctation, and aortic stenosis are more prevalent in this population.[11]A significant increase in the likelihood of being small for gestational age is seen among infants with TOF, complete AV septal defect, hypoplastic left heart, pulmonary stenosis, or large VSD.[12]

While cardiac catheterization, intervention, and complete surgical repair in the newborn of very low birth weight (<1.5 kg) can be successfully undertaken with low risk, it is notable that given the complexity of premature organ systems and superimposed cardiorespiratory pathophysiology, morbidity and mortality are increased.[13,14] Low-birth-weight neonates with complex single ventricle disease undergoing surgical palliation have a significant mortality risk.[15,16] Interventional catheterization in premature infants is associated with a higher risk for complications related to vascular access, arrhythmias, and respiratory compromise.[13] Maintenance of euglycemia and normothermia and attention to fluid and electrolyte balance are important. O_2 delivery is optimized by maintaining age-appropriate blood pressures, adequate intravascular volume, and hematocrit. Any acidosis must be sought and aggressively corrected. Whenever possible, such infants should recover in a specialized pediatric cardiac intensive care unit (ICU).

CONGENITAL HEART DISEASE

The marked array of anatomic and physiologic conditions seen with CHD distinguishes these processes from acquired adult cardiac disease. The spectrum of intracardiac shunts, valve pathologies, disrupted great artery connections, and the absence of one or more chambers of the heart preclude a uniform anesthetic approach to patients with CHD. Moreover, myocardial changes result from the hemodynamic impact and increased cardiac work incurred by these defects. Functionally, these myocardial changes place the ventricles at great risk for the development of intraoperative ischemia and failure. Therefore, an understanding of the isolated defect, associated myocardial changes, and hemodynamic consequences is fundamental to planning an appropriate anesthetic regimen. Distilling CHD into a finite number of physiologic categories enables the anesthesiologist to construct a strategy that employs the qualitatively predictable impact of drugs, ventilatory management, and fluid administration to optimize cardiovascular performance. Although an isolated heart malformation may be identified, the entire cardiopulmonary system is usually affected.

TABLE 78.1 Classification of Congenital Heart Defects

Physiologic Classification	Pulmonary Blood Flow	Comments
Left-to-right shunts		
VSD	↑	Volume-overloaded ventricle
ASD		Development of CHF
PDA		
AV canal		
Right-to-left shunts		
Tetralogy of Fallot (TOF)	↓	Pressure-overloaded ventricle
Pulmonary atresia/VSD		Cyanotic
Eisenmenger complex		Hypoxemia
Mixing lesions		
Transposition/VSD	Generally↓ but variable $\dot{Q}p/\dot{Q}s$	Variable pressure versus volume loaded
Tricuspid atresia		Usually cyanotic
Anomalous venous return		
Univentricular heart		
Obstructive lesions		
Interrupted aortic arch		Ventricular dysfunction
Critical aortic stenosis		Pressure-overloaded ventricle
Critical pulmonic stenosis		Ductal dependence
Hypoplastic left heart syndrome		
Coarctation of the aorta		
Mitral stenosis		
Regurgitant lesions		
Ebstein anomaly		Volume-overloaded ventricle
Other secondary causes		Development of CHF

ASD, Atrial septal defect; *AV*, atrioventricular; *CHF*, congestive heart failure; *PDA*, patent ductus arteriosus; $\dot{Q}p$, pulmonary blood flow; $\dot{Q}s$, systemic blood flow; *VSD*, ventricular septal defect.

Physiologic Approach to Congenital Heart Disease

Although the structural variations seen in CHD constitute an encyclopedic list of malformations, anesthetic management is more logically designed to achieve physiologic goals. A general physiologic classification is listed in Table 78.1. Fortunately, although structurally complex, these defects can be understood within a more limited physiologic spectrum. Identification and classification on the basis of physiology provide an organized framework for the intraoperative anesthetic management and postoperative care of children with complex congenital cardiac defects. In general, congenital heart lesions fit into one of four categories: shunts, mixing lesions, flow obstruction, and regurgitant valves (see Table 78.1). Each category imposes at least one of three pathophysiologic states: ventricular volume overload, ventricular pressure overload, or hypoxemia. Ultimately, these pathophysiologic conditions can result in myocardial failure or pulmonary vascular disease. Medical and surgical perioperative management strategies focus on minimizing the pathophysiologic consequences of these lesions.

Shunt Lesions. Shunts are intracardiac connections between chambers (e.g., ASD or VSD) or extracardiac connections between a systemic and pulmonary artery (e.g., PDA). The direction of blood flow through the shunt depends on the relative resistances on either side of the shunt and on the size of the shunt orifice. The direction and magnitude of shunt at the atrial level are additionally governed by the relative differences in ventricular compliance and respective AV valve function. With a nonrestrictive VSD or PDA that does not impede blood in either direction, the main determinant of the direction of blood flow is relative resistance between the pulmonary and systemic vascular beds. The effect that a shunt lesion has on the cardiovascular system depends on both the size of the shunt and its direction.

Left-to-right shunts occur when the PVR is lower than the SVR, so that blood flow is preferentially directed toward the lungs, resulting in increased PBF. In patients with large left-to-right shunts and low PVR, this increase in PBF can be substantial and result in three pathophysiologic problems: (1) congestion of the pulmonary circulation; (2) intravascular volume overload with resulting increased cardiac work for the LV; and (3) excessive PBF, resulting in progressive elevation in PVR. Volume overload causes ventricular dilation that places the heart at a mechanical and physiologic disadvantage, resulting in reduced diastolic compliance. Diastolic changes lead to engorgement of the respective venous beds, which produces the signs and symptoms of clinical congestive heart failure (CHF) early in the natural history of volume-overload condition. The demand for increased cardiac output placed on the LV is limited in the infant by virtue of its immature structure, so that large left-to-right shunts may outstrip the capacity of the left side of the heart to maintain adequate systemic perfusion.

Surgical closure of a hemodynamically significant VSD usually provides immediate benefit by dramatically lowering left ventricular volume output demands. Occasionally, the sudden increase in wall stress imposed on a dilated ventricle that must now pump solely against SVR can produce worsening ventricular failure during the early postoperative period after eliminating the low-resistance "pop off" into the pulmonary circulation. If the left-to-right shunt is not repaired, prolonged exposure to increased PBF results in progressive elevations in PVR. Fixed changes in pulmonary arterioles may occur, leading to pulmonary vascular obstructive disease, which may become irreversible. Table 78.1 lists common left-to-right shunt lesions.

Right-to-left shunts occur when pulmonary vascular or right ventricular outflow tract resistance exceeds SVR, thereby reducing PBF. The systemic circulation receives an admixture of deoxygenated blood via the shunt. This manifests clinically as cyanosis and hypoxemia. Pure right-to-left shunting resulting from increased PVR is seen in the Eisenmenger complex and persistent pulmonary hypertension of the newborn with shunt at both the atrial and ductal levels. More commonly, PVR is low, and the right-to-left shunt is produced by a more complex lesion with obstruction of pulmonary outflow proximal to the pulmonary vasculature. A classic example of right-to-left shunt is TOF, where shunting occurs through the VSD because of pulmonary outflow obstruction. Systemic perfusion is generally normal with right-to-left shunting lesions unless hypoxemia becomes severe enough to impair O_2 delivery to tissues. Right-to-left shunting produces two pathophysiologic problems: (1) reduced PBF resulting in systemic hypoxemia and cyanosis, and (2) increased impedance to right ventricular ejection, which may ultimately lead to ventricular dysfunction and RV failure. However, the physiologic mechanisms designed to compensate for pressure overload rarely create abnormalities in systolic or diastolic function early in the natural history of the disease process. In contrast to lesions that produce excessive ventricular volume, lesions that produce isolated pressure overload typically require years to cause ventricular dysfunction and failure.

TABLE 78.2 Ductal-Dependent Lesions

PDA Provides Systemic Flow	PDA Provides Pulmonary Flow
Coarctation of the aorta	Pulmonary atresia
Interrupted aortic arch	Critical pulmonary stenosis
Hypoplastic left heart syndrome	Severe subpulmonic stenosis with VSD
Critical aortic stenosis	Tricuspid atresia with pulmonic stenosis

PDA, Patent ductus arteriosus; *VSD,* ventricular septal defect.

Mixing Lesions. Mixing lesions constitute the largest group of cyanotic congenital heart defects (see Table 78.1). In these defects, the mixing between the pulmonary and the systemic circulation is so large that the systemic and pulmonary artery O_2 saturations approach each other. The pulmonary-to-systemic flow ratio $\dot{Q}p/\dot{Q}s$ is independent of shunt size, and is completely dependent on vascular resistance or outflow obstruction. The pulmonary and systemic circulations tend to be in parallel with one another rather than in series (see Table 78.1). In patients with no outflow obstruction, flow to the systemic or pulmonary circulation depends on the relative vascular resistances of both circuits, such as with univentricular hearts or double-outlet RV. If SVR exceeds PVR, as in the typical circumstance, the tendency is toward excessive PBF, and the predominant pathophysiologic process is left-to-right shunting. These patients have increased PBF, ventricular volume overload, and a gradual elevation of PVR over time. If PVR exceeds SVR, as may occur episodically in ductal-dependent lesions such as hypoplastic left heart syndrome (HLHS), systemic blood flow predominates and PBF dramatically decreases, causing hypoxemia (Table 78.2).

In patients with a mixing lesion and left ventricular outflow obstruction, PBF may be sufficiently excessive to impair systemic perfusion. In patients with mixing lesions and a right ventricular outflow obstruction, such as a single ventricle with subpulmonic stenosis, systemic-to-pulmonary flow can vary from balanced flow to significantly decreased PBF in which the severity of hypoxemia depends on the degree of obstruction. Typical mixing lesions include truncus arteriosus, univentricular heart, total anomalous pulmonary venous return, pulmonary atresia with large VSD, and single atrium.

Obstructive Lesions. Obstructive lesions range from mild to severe. Severe lesions manifest in the newborn period with a pressure-overloaded, diminutive, or profoundly dysfunctional ventricle proximal to the obstruction. Such lesions include critical aortic stenosis, critical pulmonic stenosis, coarctation of the aorta, and interrupted aortic arch. Although aortic and pulmonary atresia represent the most extreme variants of outflow tract obstruction, they are associated with such significant hypoplasia of the ventricle (HLHS and pulmonary atresia with intact ventricular septum, respectively) that the ventricle's function does not contribute to the circulatory physiology. As with other critical obstructive lesions, these extreme variants have ductal-dependent circulations, but beyond that similarity they are perhaps better understood as univentricular hearts for which the management characteristics of a mixing lesion dominate in importance.

In critical neonatal left-sided obstructive defects, systemic perfusion depends on desaturated blood flow from the RV via the PDA; the coronary perfusion is supplied by retrograde flow from the descending aorta (see Table 78.2). In right-sided lesions, PBF is supplied from the aorta via the PDA and right ventricular function is impaired.

Pathophysiologic problems in critical neonatal left-sided heart obstructive lesions include (1) profound left ventricular failure, (2) impaired coronary perfusion with an increased incidence of ventricular ectopy, (3) systemic hypotension, (4) PDA-dependent systemic circulation, and (5) systemic hypoxemia. The pathophysiologic problems in critical neonatal right-sided heart obstructive lesions include (1) right ventricular dysfunction, (2) decreased PBF, (3) systemic hypoxemia, and (4) PDA-dependent PBF. Apart from the most extreme variants that become evident in the neonatal period, infants and children with outflow obstruction (e.g., mild-to-moderate aortic or pulmonary stenosis, coarctation of the aorta) manifest compensatory mechanisms for pressure overload, and often remain clinically asymptomatic for many years.

Regurgitant Valves. Regurgitant valves are uncommon as primary congenital defects. Ebstein malformation of the tricuspid valve is the only pure regurgitant defect manifesting in the newborn period. However, regurgitant lesions are frequently associated with an abnormality of valve structure, such as incomplete or partial AV canal defect, truncus arteriosus, and TOF with an absent pulmonary valve. The pathophysiology of regurgitant lesions includes (1) volume-overloaded circulation and therefore (2) progression toward ventricular dilation and failure.

When considering the incidence of all the congenital heart defects, three uncomplicated left-to-right shunts (VSD, ASD, PDA) and two obstructive lesions (pulmonic stenosis, aortic coarctation) constitute 60% of all congenital cardiac defects. Mixing lesions, complicated obstructive defects, and right-to-left shunting lesions account for the vast majority of the remaining 40%. The latter group of defects, which are more difficult to manage, have a significantly higher morbidity and mortality rate.

Chronic Consequences of Congenital Heart Disease. The chronic effects of CHD are a consequence of the imposed hemodynamic stress of the defect or the residua and sequelae after cardiac surgery. These effects continue to alter normal growth and development of the cardiovascular system and other organ systems throughout life. Complete surgical cures are rarely achieved, and some repairs are palliative rather than corrective; therefore, abnormalities before and after repair produce long-term effects in patients with CHD.[17] Many of the abnormalities are trivial and have no major import. Others affect major organ system processes, such as ventricular function, the conduction system of the heart, central nervous system (CNS) growth, or PBF. Whether anesthetizing these patients for their primary or subsequent cardiac repair or for noncardiac surgery, these chronic changes should be ascertained and reflected in the anesthetic plan.

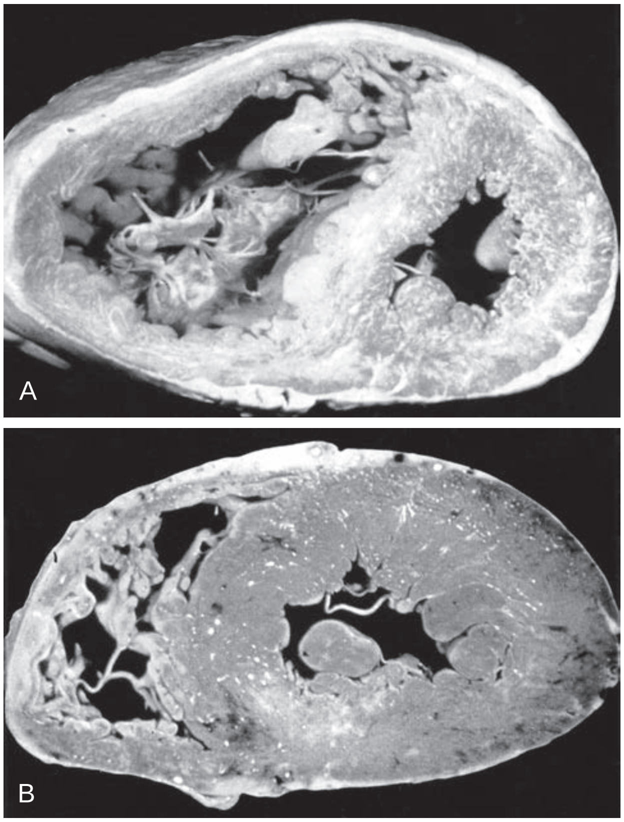

Fig. 78.2 Comparison of ventricular hypertrophy patterns demonstrating altered ventricular remodeling in two different congenital heart defects. (A) Note the right ventricular hypertrophy and the diminutive left ventricle in tetralogy of Fallot. (B) Note the severe left ventricular hypertrophy and septal bulging into the right ventricle in aortic stenosis.

The myocardium is continually remodeled by specific hemodynamic stresses in utero and throughout life. Abnormal hemodynamic loading conditions associated with CHD interrupt the normal ventricular modeling process (Fig. 78.2).[18] Abnormal ventricular remodeling typically begins in utero and stimulates an increase in ventricular mass. Increased ventricular mass is due to both hyperplasia and hypertrophy of myocytes in response to altered wall stress on the developing ventricle. The resultant biomechanical deformation of the ventricle alters its geometry, affecting normal systolic and diastolic function.

	Normal	Pressure overload	Volume overload
LVp	$\frac{117 \pm 7}{10 \pm 1}$	$\frac{220^* \pm 6}{23^* \pm 3}$	$\frac{139 \pm 7}{24^* \pm 2}$
h	.8 ± .1	1.5* ± .1	1.1* ± .1
r	2.4 ± .1	2.8 ± .2	3.3* ± .1
h/r	.34 ± .02	.58* ± .05	.34 ± .02
σ_s	151 ± 14	161 ± 24	175 ± 7
σ_p	17 ± 2	23 ± 3	41* ± 3

Fig. 78.3 Changes in ventricular physiology that accompany abnormal pressure and volume loading in human adolescents and adults. Schematic diagram represents the changes in cross-sectional ventricular geometry that accompany abnormal pressure and volume loads. Data are measured and derived from catheterization and echocardiography of 30 adolescent and adult human subjects. Pressure overload triggers significant increases in wall thickness and wall thickness-to-radius ratio *(h/r)*, but these compensatory mechanisms preserve σ within normal limits. Whereas volume overload causes dilation and enough hypertrophy to preserve normal σ_S, diastolic function deteriorates significantly. **P* = .01. σ_d, End-diastolic wall stress; σ_s, peak systolic wall stress; *h,* wall thickness (mm); *LVp,* left ventricular pressure; *r,* radius of the left ventricular chamber. (From Grossman W, Jones D, McLaurin LP. Wall stress and patterns of hypertrophy in the human left ventricle. *J Clin Invest.* 1975;56[1]:56–64.)

Abnormalities of ventricular performance at rest and with exercise can be detected in patients with chronic hemodynamic overload and complex cyanotic lesions. These abnormalities in ventricular function are the consequences of chronic ventricular overload, repeated episodes of myocardial ischemia, and residua or sequelae of surgical treatment (ventriculotomy, altered coronary artery supply, inadequate myocardial protection). Although chronic volume or pressure overload of the LV results in CHF, the compensatory mechanisms for pressure overload create less physiologic disturbance than volume overload, particularly in diastolic function. Consequently, CHF occurs later in the natural history of isolated obstructive lesions that do not require treatment in the neonatal period. Similarly, chronic right ventricular volume overload as seen in pulmonic insufficiency after TOF repair is more likely to be associated with chronic ventricular dysfunction and failure than a pressure-loaded RV that manifests with residual pulmonic stenosis. In fact, the most potent combination for inducing ventricular dysfunction and failure occurs when a pressure overload is superimposed on a dilated, volume-overloaded ventricle (e.g., postoperative TOF with pulmonary insufficiency and branch pulmonary artery stenosis).

Initial manifestations of CHF reflect alterations in ventricular compliance that result from a variety of biophysical responses to abnormal loading conditions. The ventricular dilation and compensatory hypertrophy that accompany excessive intravascular volume provide effective compensation to preserve normal systolic wall stress, but alterations in diastolic wall stress become evident (Fig. 78.3). Ultimately, chronic or severe pressure overload causes similar changes as the resultant myocardial hypertrophy outgrows vascular supply and results in ischemia and fibroblast proliferation. Permanent changes in myocardial structure and function are the end result.

In patients with cyanotic heart defects, the long-term compensation for chronic hypoxemia is major redistribution of organ perfusion with selected blood flow to the heart, brain, and kidney and decreased flow to the splanchnic circulation, skin, muscle, and bone. Chronic hypoxemia is associated with increased work of breathing in an attempt to increase O_2 uptake and delivery. The most dramatic complications are decreased rate of somatic growth, increased metabolic rate, and an increase in hemoglobin concentrations.

Congenital syndromes may have associated CHD that will influence long-term outcome (Table 78.3).

Surgical Procedures and Special Techniques. The ultimate objectives for congenital heart surgery are (1) physiologic separation of the circulation, (2) relief of outflow obstruction, (3) preservation or restoration of ventricular mass and function, (4) normalization of life expectancy, and (5) maintenance of quality of life. The available surgical procedures to accomplish these objectives are diverse and complex (Table 78.4). In general, operations performed for congenital heart defects can be divided into corrective and palliative procedures. The type and timing of repair depend on the age of the patient, the specific anatomic defect, and the experience of the surgeon and the team (see Table 78.4).

Palliation in infancy is usually performed when anatomic parts are missing, as in pulmonary atresia (absent RV and pulmonary artery), tricuspid atresia (absent RV and tricuspid valve), HLHS (aortic atresia and hypoplastic LV), univentricular heart (absent RV or LV), and mitral atresia (absent LV). These palliative procedures can be further subdivided into those that increase PBF, those that decrease PBF, and those that increase mixing (see Table 78.4). Palliative procedures that increase PBF include shunts (Blalock-Taussig, central, and Glenn), outflow patch, and enlargement of the VSD. Those that decrease PBF include pulmonary artery banding and ligation of a PDA. Those that improve intracardiac mixing include atrial septostomy (balloon, blade, and Blalock-Hanlon).

The improvements in surgical technique, coupled with advancements in anesthetic and technologic support, make repair in early infancy not only feasible but in many cases preferable.[19,20] Currently, repair in infancy can be offered for a number of congenital heart defects, as shown in Table 78.4. The timing of surgical intervention reflects medical necessity, physiologic and technical feasibility, and optimal outcome. Cardiac defects that require a PDA to sustain sufficient systemic blood flow or PBF (e.g., pulmonary atresia, HLHS, interrupted aortic arch, critical aortic stenosis, and critical pulmonic stenosis) require an intervention in the neonatal period. A variety of defects are optimally repaired in early infancy. Lesions such as transposition of the great arteries (TGA) may exhibit better left ventricular function if the arterial switch operation is performed in the first few weeks of life when the PVR has recently been high enough to increase left ventricular systolic pressure, whereas other repairs may manifest less volatile postoperative physiology if deferred a few weeks or months until PVR has consistently fallen (e.g., TOF, AV

TABLE 78.3 Syndromes Associated with Congenital Heart Disease

Syndrome	Lesion	Cardiac Lesion	Comments
SYNDROMES WITH AIRWAY ISSUES AND CHD			
CHARGE syndrome (association)		VSD, ASD, PDA, TOF	Micrognathia, possible difficult airway
Edwards syndrome	Trisomy 18	VSD, ASD, PDA	Micrognathia, small mouth, difficult intubation
Di George sequence	Microdeletion 22q11.2	Aortic arch and conotruncal lesions	Short trachea—tendency to endobronchial intubation
Goldenhar syndrome		VSD, PDA, TOF, CoA	Maxillary and mandibular hypoplasia, C-spine anomalies—difficult intubation
Hurler syndrome	MPS 1, storage disorder	Multivalvular disease, CAD, cardiomyopathy	Macroglossia, short neck—extremely difficult intubation
Noonan syndrome		PS, ASD, cardiomyopathy	Short webbed neck, macrognathia—difficult intubation
Turner syndrome	Monosomy X	LVOT O, AS, HLHS, CoA	Micrognathia, webbed neck—difficult intubation
VATER association		VSD, TOF, ASD, PDA	Potential for difficult intubation
SYNDROMES WITH RISK FOR ARRHYTHMIAS			
Long QT syndrome (LQTS)		Torsade de pointes, SCD	
Brugada syndrome		VT/VF/SCD	
Arrhythmogenic right ventricular dysplasia (ARVD)		VT/SCD	
Catecholaminergic polymorphic ventricular tachycardia		Polymorphic VT/SCD	
Wolff-Parkinson-White syndrome		SVT	
Maternal lupus		CCHB in the newborn	
CHROMOSOMAL DISORDERS ASSOCIATED WITH CHD

canal defect). Each defect may have mitigating factors for which deferred definitive repair will enable an optimal surgical result (e.g., TOF with aberrant coronary branching pattern or multiple VSDs; TGA with VSD and severe left ventricular outflow tract obstruction).

Pediatric cardiovascular surgery aims to preferentially repair defects in infancy rather than palliate.[21] This trend reflects improved technical capabilities coupled with a desire to limit the morbidity and mortality associated with long-term medical management and the sequelae

TABLE 78.4 Congenital Cardiac Defects and Their Repair

Anatomic Defects	Palliation	Complete Repair
Tetralogy of Fallot (TOF)		VSD closure and RVOT patch

of multiple palliative operations. Early correction should decrease the incidence of the chronic complications of CHD, such as the problems associated with ventricular overload, cyanosis, and pulmonary vascular obstructive disease.[22] Early repair also may have the selective advantage of enhancing organ system protection during repair because of poorly understood factors promoting resistance to injury and enhanced recovery potential (i.e., enhanced plasticity). With the continued improvement in surgical techniques and the early treatment of CHD, specific organ systems such as the brain, heart, and lungs will be spared the detrimental effects of chronic derangements of hemodynamics and O_2 delivery.

Procedures for the treatment of CHD continue to evolve to decrease long-term morbidity and enhance survival. For example, the long-term problems with right ventricular dysfunction and failure associated with the Mustard procedure for repair of TGA encouraged many surgical groups to develop the neonatal arterial switch operation, which probably provides an anatomic correction with better long-term results. A second example of the continuing evolution of technique is surgery for TOF. Long-standing pulmonary insufficiency after right ventricular outflow repair for TOF is associated with right ventricular dysfunction and failure. Preservation of the pulmonary valve at initial repair using a combined transatrial and transpulmonary approach during correction and the early insertion of a pulmonary homograft in the setting of pulmonary insufficiency are techniques employed to avoid the long-term problems of right ventricular dysfunction and failure.[23]

Surgery for HLHS, once considered a fatal disease, has achieved significant long-term survival after a series of staged reconstructive procedures.[24,25] The use of RV-PA conduits as an alternative to traditional systemic-to-pulmonary shunts confers some advantage in survival after stage 1 palliation owing to elimination of diastolic runoff into the pulmonary circulation with concurrent unloading of the systemic RV. Myocardial perfusion improves with higher diastolic pressures, no run off to the pulmonary circulation, and decreased myocardial work. The long-term impact of a right ventriculotomy in a univentricular heart is unknown.[26-28] In 2008, the Pediatric Heart Network, an organization sponsored by the National Institutes of Health, completed enrollment in a randomized control trial comparing the effects of modified Blalock-Taussig shunt (mBTS) to RV-PA conduits as part of the stage 1 Norwood procedure.[29] Recent results revealed infants treated with an RV-PA shunt had improved survival over those with mBTS, although the long-term outcomes were not different.[29,30]

Neurologic outcome after surgical repair is an ongoing concern. Preoperative cerebral blood flow (CBF) was shown to be diminished in patients with a variety of congenital heart defects, and low CBF values were associated with periventricular leukomalacia.[31] Some centers routinely advocate regional low-flow cerebral perfusion and measurement of regional cerebral O_2 saturation index and CBF velocity using transcranial Doppler imaging during arch reconstruction in this population. Reductions in the regional cerebral O_2 saturation index or CBF greater than 20% of baseline are treated aggressively in an attempt to increase cerebral O_2 delivery by increasing the mean perfusion pressure, red blood cell (RBC) transfusion, and maintenance of high normal levels of $PaCO_2$ to achieve cerebral vasodilation.

Techniques have evolved to a “three-region” perfusion strategy for aortic arch reconstruction in the Norwood procedure. This technique involves direct perfusion of the coronaries and distal thoracic aorta as well as continuous cerebral perfusion via innominate cannulation. The arch repair occurs from distal to proximal at warmer patient temperatures, theoretically allowing decreased coronary and splanchnic ischemic times, decreasing the risk of cardiac dysfunction and abdominal organ damage, and mitigating the negative hypothermic effects on the hematologic system.[32,33]

Surgical management has evolved in a broader application of certain surgical procedures initially designed for a specific defect. For example, modifications of the Fontan operation, which was originally devised for patients with tricuspid atresia, are now being used to repair a variety of univentricular hearts, including HLHS.[34,35] Initially, the wider application of the Fontan operation to include complex defects once considered inoperable was associated with a rise in morbidity and mortality. However, this trend has been reversed in recent years by several groups who have demonstrated improved outcome with the staging of the operation (superior cavopulmonary anastomosis, subsequent completion of the Fontan operation), the creation of a fenestration between the RA and LA at the time of the Fontan operation, and the use of modified ultrafiltration (MUF) at least in the early years.[36]

However, as patients who undergo the Fontan procedure grow older, they present with the unique pathophysiologic challenges of refractory arrhythmias, a failing single ventricle, protein-losing enteropathy, and plastic bronchitis. Most of these adults are cared for in a combined pediatric and adult cardiac program and require intensive multidisciplinary care to optimize cardiorespiratory status. Ingenuity and innovation such as demonstrated with the Fontan procedure have permitted continued improvements in survival for all patients with CHD. As incisions in the myocardium become smaller and sutures more precisely placed, and as improvements in surgical techniques continue to evolve, the complications of ventricular dysfunction, arrhythmias, and residual obstruction should decline, contributing to improved patient quality of life.

One final difference unique to congenital heart surgery that has a major impact on anesthetic management relates to the type of cardiopulmonary support. Because of the complexity of repair in small patients, surgery often requires significant alterations in the bypass techniques, such as the use of deep hypothermic CPB at temperatures of 18°C and total circulatory arrest. Despite widespread use of these techniques during CPB, their physiologic effects on major organ system function are just beginning to be understood. These effects are discussed in subsequent sections.

Anesthetic Management

PREOPERATIVE MANAGEMENT

Anesthetic Evaluation

Caring for children with CHD presents the anesthesiologist with a wide spectrum of anatomic and physiologic abnormalities. Patients range from young, healthy, asymptomatic children who are having closure of a small ASD to the neonate with HLHS requiring aggressive perioperative hemodynamic and ventilatory support. Intertwined with the medical diversity of these patients are the psychological factors affecting both the patient and their parents. Preparation of the patient and the family is time-consuming, but omitting or compromising this aspect of patient care is a major deterrent to a successful outcome and patient and parental satisfaction. This team-oriented approach also serves as a safeguard to prevent errors and omissions in the exacting perioperative care necessitated by the complexity of cardiac surgery for CHD. The preoperative visit offers the family the opportunity to meet the surgeon and anesthesiologist.

Parents should be questioned about the general health and activity of their child. Fundamentally, a child's general health and activity will reflect cardiorespiratory reserve. Deficiencies may point toward cardiovascular or other systems that may influence anesthetic or surgical risk. Does the child have impaired exercise tolerance? Is the child gaining weight appropriately, or exhibiting signs of failure to thrive on the basis of cardiac cachexia? Does the child exhibit signs of CHF (diaphoresis, tachypnea, poor feeding, recurrent respiratory infections)? Is there progressive cyanosis or new onset of cyanotic spells? Any intercurrent illness such as a recent upper respiratory tract infection or pneumonia must be ascertained. Lower respiratory tract infections may require a delay in proposed surgery, based on the negative impact that airway reactivity and elevations in PVR may have on surgical outcome. Recurrent pneumonia is frequently associated with pulmonary overcirculation and altered lung compliance in patients with increased PBF.

A good history will delineate previous surgical and cardiologic interventions, which may impact both surgical and anesthetic plans for the current procedure. Patients who have had their subclavian artery sacrificed for a subclavian flap angioplasty to correct coarctation or a Blalock-Taussig shunt will not accurately display systemic arterial pressure or perhaps even pulse oximetry readings when the monitoring is applied to the affected side. Likewise, children who have femoral venous occlusion after catheterization are not candidates for femoral venous access, particularly for femoral CPB should sternotomy prove impossible. It is equally important to obtain current medications, previous anesthetic problems, and family history of anesthetic difficulties.

In the modern era of echocardiography and cardiac catheterization, physical examination rarely contributes additional anatomic information about the underlying cardiac lesion. However, it is extremely useful in assessing the overall clinical condition of the child. For example, an ill-appearing, cachectic child in respiratory distress has limited cardiorespiratory reserve and the use of excessive premedication or a prolonged inhaled induction of anesthesia could result in significant hemodynamic instability.

Concurrent Medications and Drug Interactions

Drug interactions are common both among the co-therapeutic cardiovascular agents and between hemodyamic drugs and anesthetic drugs. An understanding of the mechanisms and interactions is useful to the pediatric cardiovascular anesthesiologist. Some common cardiovascular medications and anesthesia considerations are shown in Table 78.5.

Pediatric oncology patients presenting for cardiac or noncardiac procedures may manifest higher cardiovascular risk because of cardiotoxic chemotherapy.[37] Common cardiotoxic agents include the antimetabolite 5-fluorouracil, the anthracycline antibiotics doxorubicin and daunorubicin, and the alkylating agent cyclophosphamide. The acute form of toxicity is characterized by acute ST segment/T wave changes on the electrocardiogram (ECG), serious dysrhythmias, and CHF associated with pericardial effusion. Chronic cardiotoxic HF is cumulative, dose related, and unresponsive to digoxin therapy. Serious cardiomyopathy can occur and is related to dose, irradiation, and use of an anthracycline. The mortality rate can

TABLE 78.5 Common Perioperative Medications and Considerations

Cardiac Drug Class	Interactions	Considerations
Angiotensin-converting enzyme inhibitors	Hypotension with induction of general anesthesia	Consider withholding morning dose, or reducing dosage, in hypotensive patients; avoid fixed dose induction regimens with drugs having a profound vagomimetic effect
β-Blockers	Acute withdrawal can precipitate tachycardia and arrhythmias; can potentiate hypotension with volatile anesthesia; can decrease response to inotropic agents	Continue in the perioperative period
Calcium channel blockers	May augment the negative inotropic and chronotropic effects of volatile anesthesia	Continue in the perioperative period
Diuretics	Hypovolemia/hypokalemia; may augment effect of neuromuscular blocking agents	Discontinue preoperatively
Antiarrhythmics	Can be proarrhythmic with inotropes, electrolyte disturbances; high catecholaminergic states; can interact with other antiarrhythmics and precipitate bradycardia	Avoid electrolyte imbalance Avoid drugs that are proarrhythmic Monitor carefully
α_2-Agonists	Reduces perioperative shivering, ischemia, anesthetic and analgesic requirements	Continue into the perioperative period with appropriate monitoring

exceed 50%. These patients should undergo thorough preoperative evaluation, including a full blood cell count, assessment of renal and hepatic function and coagulation parameters, and an echocardiogram. An isoflurane/nitrous oxide (N_2O)-based anesthetic might confer better hemodynamic stability than opioid-based anesthesia in such patients.[38]

Anesthetics can induce torsade de pointes, a malignant arrhythmia. Risk factors include female gender, electrolyte imbalances such as hypokalemia and hypomagnesemia, genetic ion channel polymorphisms of congenital long QT syndrome (LQTS), subclinical LQTS, baseline QT prolongation, and use of QT-prolonging drugs especially in high concentrations or as rapid intravenous infusions. Conditions with reduced repolarization reserve such as CHF or digoxin toxicity can also precipitate torsade de pointes. Drugs that may cause torsade de pointes in patients with congenital LQTS are shown in Table 78.6. The website https://crediblemeds.org provides an updated list of drugs that prolong the QT interval.

Traditionally, patients undergoing cardiac surgery have blood drawn for laboratory evaluation as standard of care (hemoglobin, electrolytes, type, and screen). Recently the utility of this practice has been questioned especially in the patient coming from home. These tests are expensive, utilize significant hospital resources, cause pain and anxiety to the patient, and rarely lead to a change in care.[39] A more thoughtful, directed, and individualized strategy can limit costs and discomfort without sacrificing patient safety. On the other hand, special populations such as patients with trisomy 21, cyanotic heart disease, and those on antiplatelet therapy may require additional specific testing.

An increased hematocrit in a normovolemic child gives an indication of the magnitude and chronicity of hypoxemia. A hematocrit more than 60% may predispose to capillary sludging and secondary end organ damage, including stroke. Despite these risks, liberalized guidelines for nothing by mouth that permit children to consume clear liquids up to 2 hours before anesthetic induction have virtually eliminated the need to admit these patients to the hospital early for preoperative intravenous hydration.[40,41]

TABLE 78.6 Drugs That May Cause Torsade De Pointes in Patients With Congenital Long QT Syndrome

Drug Category	Drug Name
Antiarrhythmics	Amiodarone Procainamide Disopyramide Ibutilide Quinidine Sotalol
Antipsychotics	Chlorpromazine Haloperidol Thioridazine Mesoridazine
Antimicrobials	Erythromycin Clarithromycin
Miscellaneous	Cisapride Arsenic Methadone Droperidol Domperidone Dolasetron Ondansetron Glycopyrrolate

Echocardiography with Doppler color flow imaging (echo-Doppler) is an invaluable tool that provides a noninvasive means of assessing intracardiac anatomy, blood flow patterns, and estimates of physiologic data.[42] For many cardiac defects, more invasive studies are generally not required if a good echocardiographic assessment is made. Echo-Doppler imaging is especially helpful for defining intracardiac abnormalities. Extracardiac abnormalities, such as pulmonary artery or vein stenosis, are more difficult to define by echo-Doppler and may require computed tomography (CT) or cardiac catheterization. The ability to interpret anatomy and physiology accurately requires a skilled echocardiographer, reaffirming the need for a well-integrated interactive team. Although the complexities posed by extreme anatomic variation and changing loading conditions render intraoperative echo-Doppler challenging even for experienced echocardiographers, the pediatric cardiac anesthesiologist should develop some familiarity with its capabilities and limitations so as to participate in critical intraoperative management decisions.

Magnetic resonance imaging (MRI) of the heart and major vessels has become a very useful noninvasive imaging tool in children with heart disease. Typically, MRI is used for segmental description of cardiac anomalies; evaluation of thoracic aortic anomalies; noninvasive detection and quantification of shunts, stenoses, and regurgitations; evaluation of conotruncal malformations and complex anomalies; identification of pulmonary and systemic venous anomalies; and postoperative studies and evaluation of CHD in adult patients.[43,44] MRI is particularly useful in quantifying ventricular function, regional wall motion, valvular competence, and velocity flow mapping. It is especially useful for imaging the aortic arch, pulmonary arteries, and the mediastinal vessels in children with complex CHD. Lesions for which MRI provides accurate and useful information include coarctation of the aorta, anomalies of the pulmonary arteries, anomalous pulmonary venous connections and persistent left superior vena cava, and intracardiac baffles, conduits, and shunts.[43,44] MRI is also useful in older patients with poor acoustic windows and patients with chest wall deformities. It may be an alternative to cardiac catheterization in select patients and may provide noninvasive assessment of coronary anomalies, myocardial perfusion defects, and the detection of conditions associated with myocardial scarring (e.g., arrhythmogenic RV dysplasia). Even more novel, MRI images are now being used to reconstruct complex lesions using 3D printers to build a model of the heart to help plan the surgical procedure.[45,46] Adenosine stress cardiac MRI is used to delineate areas of inducible ischemia. However, physiologic data such as O_2 saturations cannot be obtained with MRI.

Anesthetic considerations remain the same as for all cardiac lesions, with the additional concerns for MRI safety and restricted access to an anesthetized patient with suboptimal monitors. MRI scans are prolonged and traditionally require absolute patient immobility, with control of ventilator parameters to obtain optimal images. However, with advances in technology such as respiratory gating and use of free-breathing protocols, images can be acquired with the patient spontaneously breathing. This eliminates the need for general anesthesia with an endotracheal tube and breath-holds, thus allowing for intravenous sedation with spontaneous breathing instead.

Cardiac catheterization remains the gold standard for assessing anatomy and physiologic function in CHD. Although many anatomic questions can now be reliably answered noninvasively, catheterization remains a vital tool for cases that present complex anatomic questions or require knowledge of physiologic data. Important catheterization data for the anesthesiologist include the following:

1. Child's response to sedative medications
2. Pressure and O_2 saturation in all chambers and great vessels
3. Location and magnitude of intracardiac and extracardiac shunt $\dot{Q}p/\dot{Q}s$
4. PVR and SVR
5. Chamber size and function
6. Valvular anatomy and function
7. Distortion of systemic or pulmonary arteries related to prior surgery
8. Coronary artery anatomy
9. Anatomy, location, and function of previously created shunts
10. Acquired or congenital anatomic variants that might have an impact on planned vascular access or surgery

Careful review of the cardiac catheterization data and an understanding of their potential impact on the operative and anesthetic plan are essential. Not all medical problems can be evaluated and corrected preoperatively; the surgeon, cardiologist, and anesthesiologist must discuss the potential management problems and need for further evaluation or intervention before arrival in the operating room. Appropriate communication and cooperation will optimize patient care and facilitate perioperative clinical management.

INTRAOPERATIVE MANAGEMENT

Operating Room Preparation

Advance, careful preparation of the operating room and anesthesia equipment is essential. The anesthesia machine must have the capacity to provide air, O_2, and N_2O to help balance pulmonary and systemic blood flow. Some anesthetic machines may be equipped with carbon dioxide (CO_2) as an additional gas that can be added to help balance the circulations. NO is invaluable to help lower the PVR and is usually added into the inspiratory limb of the circuit via a separate machine, which then also allows continuous NO administration, also while transporting the patient. Intravenous tubing must be free from air bubbles to prevent paradoxical air embolism, and air filters should be added to all infusion lines. Resuscitative drugs, labeled and ready for administration, should include succinylcholine, calcium gluconate or calcium chloride, sodium bicarbonate, atropine, lidocaine, phenylephrine, and epinephrine. An inotropic infusion, usually epinephrine or dopamine, should be premixed and ready for administration in high-risk cases, but additional infusions are prepared if their need is strongly suspected (e.g., milrinone, vasopressin). For all pediatric cases, certain anesthetic drugs should be available (etomidate, propofol, ketamine). No single drug can be recommended; how a particular drug is used is more important. In pediatric cardiac anesthesia, many patients have limited reserve and high endogenous catecholamine levels released in an adaptive response to their underlying cardiac disease. The resuscitative drugs should therefore be prepared and immediately available before anesthetic induction.

BOX 78.2 Monitoring of Organ Systems

Cardiopulmonary System

- Esophageal stethoscope
- Electrocardiogram
  - Standard five-lead system, ST-T wave analysis, esophageal electrocardiographic lead
- Pulse oximetry
- Automated oscillatory blood pressure
- Capnograph
- Ventilator parameters
- Indwelling arterial catheter
- Central venous pressure catheter
- Pulmonary artery catheter
- Transthoracic pressure catheter
  - Left or right atrium, pulmonary artery
- Echocardiography with Doppler color flow imaging
  - Epicardial or transesophageal

Central Nervous System

- Peripheral nerve stimulator
- Processed electroencephalography
- Specialized
  - Cerebral blood flow: Xenon clearance methodology
  - Cerebral metabolism: Near-infrared spectroscopy, oxygen consumption measurements
  - Transcranial Doppler
  - Jugular venous bulb saturations

Temperature

- Nasopharyngeal, rectal, esophageal, tympanic

Renal Function

- Foley catheter

For congenital heart surgery, the ability to alter body temperature rapidly for cooling and rewarming is essential. During deep hypothermic CPB, patients are cooled to 18°C. Surface cooling with a heating and cooling water mattress, ice in watertight bags, and an efficient room and ambient temperature control system are important in the operative management of these patients.

Physiologic Monitoring

The specific monitoring used should depend on the child's condition and the magnitude and nature of the planned surgical procedure. The perioperative monitoring techniques available are listed in Box 78.2. Noninvasive monitoring equipment is ideally placed before induction of anesthesia, although the anesthesiologist may elect to defer application of monitoring devices in the crying child until immediately after the induction. Standard monitoring includes electrocardiography, pulse oximetry, capnography, and an appropriate-sized blood pressure cuff (either oscillometric or Doppler). Additional monitoring includes an indwelling arterial catheter and temperature probes. Foley catheters are generally employed when surgical intervention entails CPB or might produce renal ischemia, or when the anesthetic management includes a regional technique associated with urinary retention. Most centers routinely employ percutaneously placed central venous pressure (CVP) monitoring or alternatively, directly placed transthoracic atrial lines by the surgeons to help with separation from CPB and the hemodynamic management in the postoperative period.

Continuous monitoring of arterial pressure is possible only through an indwelling intraarterial catheter. In young children, cannulation of the radial artery with a 22- or 24-gauge catheter is preferred. In older children and adolescents, a 20-gauge catheter may be substituted. Careful inspection, palpation, four-extremity noninvasive blood pressure determinations, and ultrasound use help ensure that previous or currently planned operative procedures (e.g., a previous radial artery cutdown, subclavian flap for coarctation repair, or Blalock-Taussig shunt) do not interfere with the selected site of arterial pressure monitoring. Other sites available for cannulation include the ulnar, femoral, axillary, and umbilical (in neonates) arteries. Cannulation of the posterior tibial or dorsalis pedis arteries is not usually sufficient for complex operative procedures. Peripheral arterial catheters, principally of the distal lower extremities, function poorly after CPB and do not reflect central aortic pressure when distal extremity temperature remains low.[47]

Myocardial and cerebral preservation is maintained principally through hypothermia; therefore, the accurate and continuous monitoring of body temperature is crucial. Rectal and nasopharyngeal temperatures are monitored because they reflect core temperature and brain temperature, respectively. Monitoring of esophageal temperature is a good reflection of cardiac and thoracic temperature. Tympanic probes, although a useful reflection of cerebral temperature, can cause tympanic membrane rupture.

Pulse oximetry and capnography provide instantaneous feedback concerning adequacy of ventilation and oxygenation. They are useful guides in ventilatory and hemodynamic adjustments to optimize $\dot{Q}p/\dot{Q}s$ before and after surgically created shunts and pulmonary artery bands. Peripheral vasoconstriction in patients undergoing deep hypothermia and circulatory arrest renders digital O_2 saturation probes less reliable. In the newborn, the use of a tongue sensor has been advocated to provide a more central measure of O_2 saturation, with less temperature-related variability.[48]

The use of transthoracic or transvenous pulmonary artery catheters is determined on an individual basis based on the disease process, physiologic state, and surgical intervention. For example, in children undergoing a Fontan procedure for tricuspid atresia or a univentricular heart, catheters in the Fontan pathway and the pulmonary venous atrium are especially useful. After a Fontan operation, PBF must occur without benefit of a ventricular pumping chamber. Subtle changes in preload, PVR, and pulmonary venous pressure will influence PBF and thus systemic cardiac output. Data derived from the difference between the CVP and left atrial pressure ([LAP]; also known as the transpulmonary gradient) help identify the relative importance of intravascular volume (CVP), PVR (CVP-LAP gradient), or ventricular compliance (LAP), each of which requires a different therapeutic approach.

As a general guideline, a transvenous pulmonary artery catheter may be placed using the internal jugular approach in children weighing more than 7 kg. A 5.0-Fr catheter is used for children weighing between 7 and 25 kg, and a 7.0-Fr one is used for children weighing more than 25 kg. For infants weighing less than 7 kg, percutaneous placement of a pulmonary artery catheter can be performed from the femoral vein. Occasionally, the latter technique will require

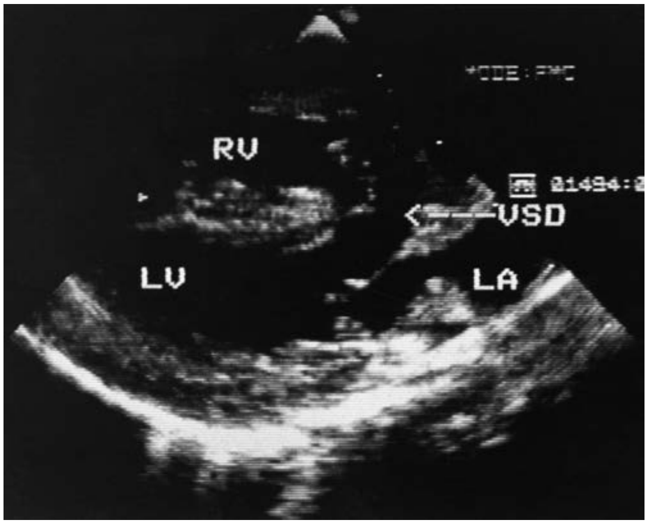

Fig. 78.4 Intraoperative pre–cardiopulmonary bypass epicardial echocardiogram in the long-axis view. Note the insertion of the papillary muscle of the tricuspid valve on the interventricular septum. On the basis of this view, the surgeon decided that ventricular septal defect *(VSD)* closure was possible in a child thought preoperatively to be a candidate for only palliation. *LA,* Left atrium; *LV,* left ventricle; *RV,* right ventricle.

fluoroscopy. The use of intraoperative transthoracic monitoring lines and echo-Doppler imaging limits the need for transvenous pulmonary artery catheters in most cases.

Special Monitoring

Intraoperative Echocardiography. The use of echo-Doppler imaging is now regarded as standard of care for almost all pediatric cardiac surgeries.[49,50] Two-dimensional echocardiography combined with pulsed-wave Doppler ultrasonography and color flow mapping provide detailed morphologic and physiologic information in the majority of operative cases. Using echo-Doppler in the operating room, anatomic and physiologic data can be obtained before CPB, thus refining the operative plans. Prebypass echo-Doppler precisely defines anesthetic and surgical management.[49] Because of the unrestricted epicardial and TEE approaches in anesthetized patients, new findings are frequently discovered and management plans changed accordingly (Fig. 78.4).

Postbypass echo-Doppler evaluation is able to immediately assess the quality of the surgical repair and cardiac function by examining ventricular wall motion and systolic thickening.[49] This technique can show residual structural defects after bypass, which can be immediately repaired, thus avoiding the patient leaving the operating room with significant residual structural defects that will require reoperation at a later time (Fig. 78.5). By identifying patients with right or left ventricular contraction abnormalities after bypass, as determined by a change in wall motion or systolic thickening, echo-Doppler provides guidance for immediate pharmacologic interventions. Importantly, postbypass ventricular dysfunction and residual structural defects identified by echo-Doppler imaging are associated with an increased incidence of reoperation and higher morbidity and mortality rates. Thus, this monitoring tool is helpful in assessing surgical repair and identifying operative risk factors, which will hopefully improve outcomes.

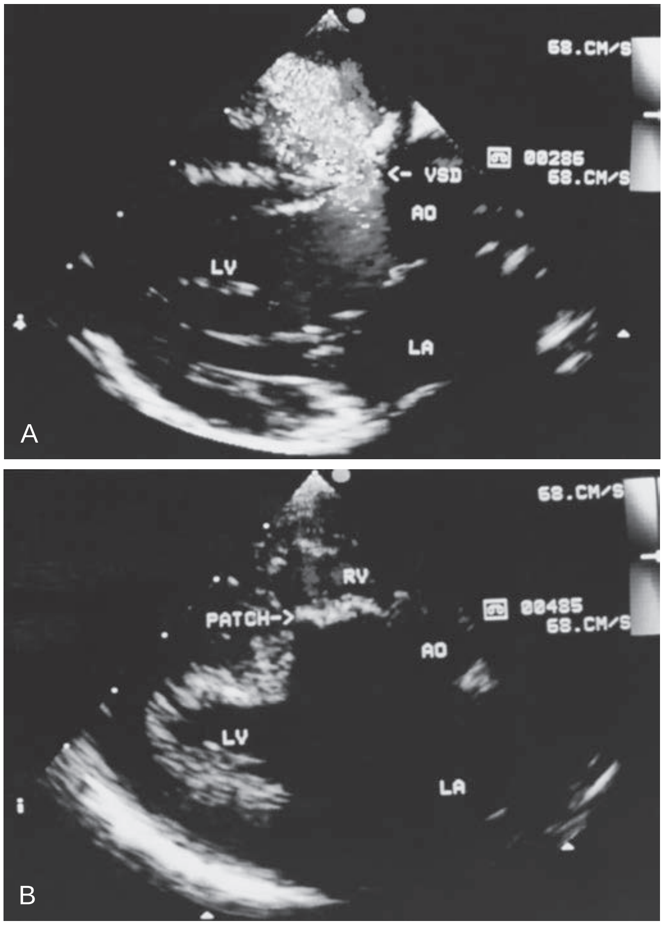

Fig. 78.5 (A) Echocardiogram with a Doppler flow map in the long-axis view illustrating a residual ventricular septal defect *(VSD)* resulting from patch dehiscence after initial repair. Turbulent flow through the VSD appears as a mosaic of white particles *(arrow)*. This finding necessitated immediate reinstitution of cardiopulmonary bypass and repeat repair. (B) Repeat Doppler flow map in the long-axis view illustrates patch closure *(arrow)* of the VSD after repeat repair. Note the absence of turbulent flow with the loss of the mosaic of white particles. *AO,* Aorta; *LA,* left atrium; *LV,* left ventricle; *RV,* right ventricle.

Two techniques for intraoperative echo-Doppler imaging have been described: epicardial and TEE. Using TEE, the probe is placed after induction of anesthesia and intubation and is then available for monitoring of the patient. The advantage of this technique is its utility as a continuous monitor of cardiac structure and function, without interrupting surgery.[49,51] Because of its ideal imaging location, TEE has been especially helpful in evaluating pulmonary venous return and the integrity of the left AV valve after mitral valvuloplasty, complete AV valve repair, and correction of complex CHD. Early limitation in views has been virtually eliminated as a result of clinical experience and improved biplane images. Pediatric biplane TEE probes have now extended the patient weight limits to neonates between 2.5 and 3 kg.[52] Potential hazards of TEE that merit particular vigilance include descending aorta and airway compression because of probe size or during probe flexion. There have been reports of esophageal damage during hypothermia and low or no flow states because of the heat energy the probe produces while connected to the TEE machine, leading most institutions to pause the imaging ability of the probe, disconnect the probe from the machine, or even remove it during the CPB period of the procedure.

A second technique for intraoperative echocardiographic analysis in children is the epicardial approach.[52] This approach requires passing a clean, short-focused 5.0- or 7.0-MHz transducer over the anesthesia screen into a sterile sheath, where it then can be placed on the epicardial surface of the heart. This technique best facilitates the probe manipulations necessary for thorough interrogation of the major structures and dynamic function of the heart. The advantage of this approach is that all views can be obtained in patients of any size. Among the disadvantages are the need for sufficient operator skill and experience to perform the manipulations, the need to interrupt surgery to manipulate the probe, and the possible deleterious impact of direct myocardial mechanical manipulation. Given current TEE capabilities, epicardial imaging is rarely employed.

Specialized Central Nervous System Monitoring. The primary goal of brain monitoring is to improve our understanding of cerebral function during cardiac surgery so that effective brain protection strategies can be developed. Because many of the determinants of normal brain perfusion become externally controlled by the cardiac team during CPB, such as flow rate (cardiac output), perfusion pressure, temperature, hematocrit, and $PaCO_2$, a knowledge of the effect of these factors on the brain in neonates, infants, and children is essential. Numerous intraoperative techniques have been used for monitoring the brain to prevent secondary brain injury from hypoxia, ischemia, emboli, and electrophysiologic derangements. These have primarily included the following three modalities in isolation or combination: (1) electroencephalography (EEG) to assess perfusion-related changes in cortical activity; (2) transcranial Doppler imaging to measure arterial flow and resistance; and (3) near-infrared spectroscopy (NIRS) to provide a measure of venous-weighted, tissue oxyhemoglobin saturation. Additionally, the measurement of CBF and metabolism with specialized clinical research tools has been very important in furthering our understanding of brain function during and after surgery. Multimodal neurologic monitoring is also used to guide CPB, deep hypothermic circulatory arrest (DHCA), and regional low-flow cerebral perfusion techniques in neonatal arch reconstruction.[53-55]

Electroencephalographic monitoring allows detection of ischemia or recognition of an adequate decrease in cerebral metabolic activity during hypothermia before DHCA. EEG is helpful in monitoring physiologic functions of the CNS during deep hypothermic bypass and total circulatory arrest. For example, during deep hypothermia and before total circulatory arrest, the processed EEG can identify residual cerebral electrical activity. Isoelectric silence can then be induced by further cooling and any further brain activity detected by EEG. Because this residual electrical activity during arrest is associated with ongoing cerebral metabolism, an isoelectric state may prevent ischemic injury to the brain during circulatory arrest. EEG also may be useful in detecting the level and depth of anesthesia. Postoperative electroencephalographic analysis has demonstrated subclinical seizure activity in a number of high-risk patients, potentially linking these abnormalities to poorer neuropsychologic outcome. The value of intraoperative electroencephalographic monitoring after CPB and the significance of the findings remain to be determined.

Transcranial Doppler imaging has been used primarily for research purposes in infants and allows detection of venous or arterial flow abnormalities and the detection of microemboli.[56] This technology uses the Doppler principle to detect shifts in the frequency of reflected signals from blood in the middle cerebral artery to calculate blood flow velocity.[57] Because the diameter of this large cerebral artery is relatively constant, flow velocity can be used to approximate CBF. Transcranial Doppler imaging has several advantages: (1) it is noninvasive, (2) it does not require radiation exposure, (3) it is a continuous monitor, and (4) it captures rapid alterations in blood flow velocity caused by temperature or perfusion changes. The limitations of transcranial Doppler monitoring include (1) reproducibility, especially at low flow rates, when small movements of the patient's head can dramatically alter the signal, and (2) the lack of validating studies during hypothermic CPB, when hypothermia, reduced flow rates, and the laminar flow characteristics of non-pulsatile perfusion may limit the accuracy of CBF velocity measurements.

Transcranial Doppler imaging has been used to investigate the effect of CPB and DHCA on cerebral hemodynamics in children, as well as to assess the incidence of cerebral emboli. Recent studies examining the brain using transcranial Doppler have enabled several investigative groups to provide important information regarding questions of normal and abnormal brain perfusion during cardiac surgery in children. Questions regarding cerebral perfusion pressure, autoregulation, effect of $PaCO_2$, and temperature have been addressed using transcranial Doppler imaging in children.[58-60] This technique also has provided qualitative information regarding the presence of gaseous emboli in the middle cerebral artery during cardiac surgery.[61]

NIRS is a noninvasive monitor of cerebral tissue oxygenation, reflecting the balance of O_2 delivery and consumption. Cerebral NIRS reflects O_2 saturation of the venous compartment, and values correlate with jugular venous bulb saturations.[62] There is significant interest in studying the ability of NIRS to predict outcomes, particularly on the neurodevelopmental spectrum. A study of infants undergoing the stage 1 Norwood procedure for HLHS demonstrated an association between low NIRS (particularly when less than 50%-60%) and poor neurodevelopmental outcomes.[63] Although there was not a linear association, it provides evidence that NIRS can be used to detect clinically consequential hypoxia. Somatic and cerebral saturations are further clinically relevant in the immediate postoperative period by predicting overall morbidity and mortality in patients with HLHS stage 1 palliation.[64] The number of minutes of cerebral desaturation below 50% predicts morbidity and serves as an early warning sign for hypoxia, bleeding, and/or low cardiac output state.[65] A decrease of greater than 20% from baseline in renal saturation as detected by NIRS for a period of 20 minutes has been associated with a longer duration of mechanical ventilation and ICU convalescence.[66]

A 2016 review of NIRS use in pediatric cardiac surgery identified several prospective trials, mostly observational, that found inconsistent results overall regarding improved

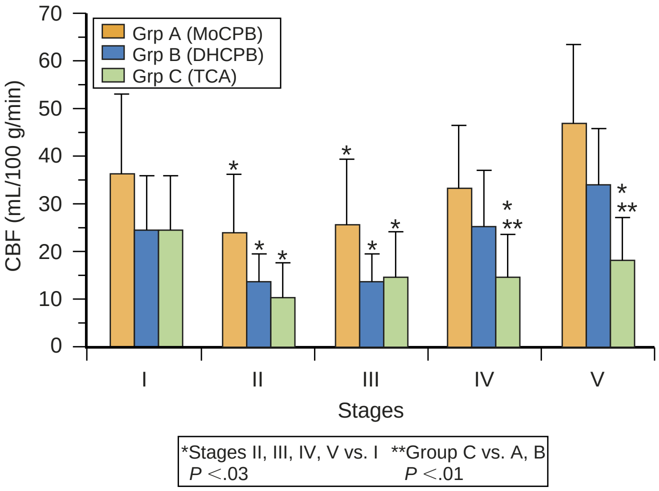

Fig. 78.6 Bar chart of the changes in cerebral blood flow *(CBF)* before, during, and after cardiopulmonary bypass *(CPB)* in 67 infants and children (mean ± SD). Group A underwent repair with moderate hypothermic bypass *(MoCPB)* at 28°C to 32°C; group B, with deep hypothermic bypass at 18°C to 22°C; and group C, with total circulatory arrest *(TCA)* at 18°C. Note the impaired cerebral reperfusion after total circulatory arrest (group C). Stage I, prebypass; stages II and III, during hypothermic bypass; stage IV, rewarmed on bypass; stage V, after bypass. (From Greeley WJ, Brusino FG, Ungerleider RM, et al. The effects of cardiopulmonary bypass on cerebral blood flow in neonates, infants, and children. *Circulation*. 1989;80:I209.)

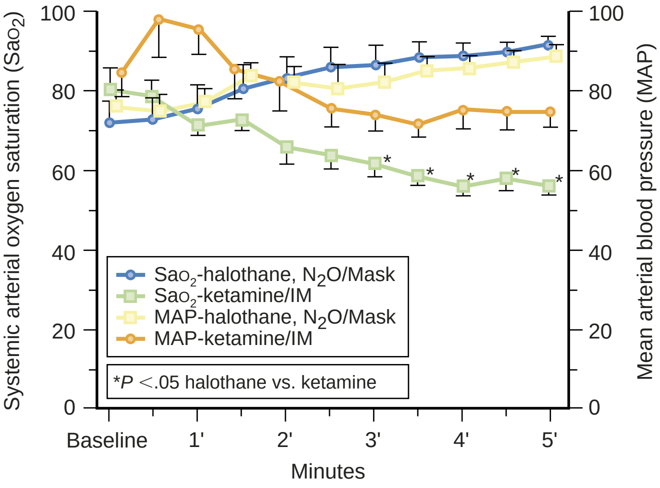

Fig. 78.7 Comparative changes in arterial oxygen saturation *(Sao$_2$)* and mean arterial pressure *(MAP)* during mask halothane nitrous oxide (*n* = 7) and intramuscular ketamine (*n* = 7) inductions in children with tetralogy of Fallot at risk for right-to-left shunting. Note the maintenance of Sao$_2$ in the halothane group despite the significant drop in MAP. *N_2O*, Nitrous oxide. (From Greeley WJ, Bushman GA, Davis DP, et al. Comparative effects of halothane and ketamine on systemic arterial oxygen saturation in children with cyanotic heart disease. *Anesthesiology*. 1986;65:666–668.)

clinical outcomes with NIRS use.[67] Importantly, the current evidence does not provide clear thresholds for cerebral or somatic NIRS, below which the chance of morbidity would increase. Differences in longer-term cardiac, renal, or neurodevelopmental outcomes have not been demonstrated based on differences in NIRS values. Despite these reservations, NIRS remains an important clinical tool to interpret alongside other monitoring technologies.

CBF studies using xenon clearance technology have improved the understanding of cerebrovascular dynamics in young children during CPB and especially during deep hypothermia and after periods of circulatory arrest.[68-71] In general, this investigational tool has described the effects of CPB, temperature, and various perfusion techniques on CBF and, indirectly, on brain metabolism (Fig. 78.6). Studies using this methodology have shown that some of the mechanisms of CBF autoregulation, such as pressure-flow regulation, are lost with deep hypothermia and that cerebral reperfusion is impaired after a period of total circulatory arrest.

Induction and Maintenance of Anesthesia

The principles of intraoperative management of cardiothoracic surgical procedures are based on an understanding of the pathophysiology of each disease process and a working knowledge of the effects of the various anesthetic and other pharmacologic interventions on a particular patient's condition. Selecting a technique for induction of anesthesia needs to consider the degree of cardiac dysfunction, the cardiac defect, the degree of sedation provided by the premedication, and the presence of an indwelling catheter. In children with good cardiac reserve, induction techniques can be quite varied in well-monitored patients. The titration of anesthetics for induction of anesthesia is more important than the specific anesthetic technique in patients with reasonable cardiac reserve. A wide spectrum of anesthetic induction techniques have been used safely and successfully, including sevoflurane, isoflurane, N_2O, intravenous and intramuscular ketamine, and intravenous propofol, fentanyl, and midazolam.[72] Ketamine is often used in anesthetic induction in patients with cyanotic conditions because it increases SVR and cardiac output, thereby diminishing the magnitude of right-to-left shunting. Administration of ketamine can be intravenous or intramuscular, with the caveat that an intramuscular injection may result in pain, agitation, and subsequent arterial desaturation.

Inhaled inductions are generally well received and tolerated by most children. An inhaled induction of anesthesia with sevoflurane can easily and safely be performed even in cyanotic patients, such as those with TOF (Fig. 78.7). In these patients, who are at risk for right-to-left shunting and systemic desaturation, oxygenation is well maintained with a good airway and ventilation despite reduction in systemic arterial pressure.[73] Skilled airway management and efficiency of ventilation are equally essential components of anesthetic induction. Recognizing the complexities of shunts and vascular resistance changes, as well as airway and ventilation effects on the cardiovascular system, is of primary importance during the induction of anesthesia.

After anesthetic induction, intravenous access is established or augmented as appropriate. A nondepolarizing muscle relaxant is usually administered and an intravenous opioid and/or inhaled anesthetic chosen for maintenance of anesthesia. The child is preoxygenated with 100% FiO$_2$, and an endotracheal tube is carefully positioned. Some degree of alveolar preoxygenation is recommended, even in the infant whose systemic perfusion might be jeopardized by lowering PVR with resulting increase in PBF, as this maneuver delays desaturation during intubation. A nasal route is usually selected in neonates and other patients who will remain intubated postoperatively, as it may provide greater stability and patient comfort than an oral endotracheal tube. However, with the trend of earlier and even intraoperative extubation, as well as new data showing an association between nasal intubation and increased infections in children older than 6 months of age, the prevalence of nasal intubation has decreased. If the child arrives in the operating room with an endotracheal tube in place, it is prudent to assess the depth and the overall state of the endotracheal tube. Inspissated secretions in a tube with a small internal diameter can cause significant obstruction to gas flow and may be made worse during periods of bypass when humidified ventilation is discontinued. This may be minimized by placing a new endotracheal tube at the beginning of the procedure.

Because of the diverse array of congenital heart defects and surgical procedures, an individualized anesthetic management plan is essential. The maintenance of anesthesia in these patients depends on the age and condition of the patient, the nature of the surgical procedure, the duration of the CPB, and the need for postoperative ventilation. An assessment of the hemodynamic objectives designed to lessen the pathophysiologic loading conditions should be developed for each patient, taking advantage of the known qualitative effects of specific anesthetic drugs and ventilatory strategies. These individualized plans must also be integrated with the overall perioperative goals to configure the optimal anesthetic. In patients with complex defects requiring preoperative inotropic and mechanical ventilatory support, a carefully controlled induction and maintenance anesthetic with a potent opioid is generally chosen. In patients with a simple ASD or VSD, a balanced anesthetic with inhaled anesthetics, opioid titration, and the use of dexmedetomidine is preferred. This allows for intraoperative tracheal extubation and a less prolonged period of intensive care monitoring. More important than the specific anesthetic techniques and drugs is the skilled execution of the anesthetic plan, taking into account patient response to drugs, the changes associated with surgical manipulation, and early recognition of intraoperative complications.

The reported changes in arterial blood pressure and heart rate from the inhaled anesthetic in normal children are observed in pediatric cardiac surgical patients as well. We use potent inhaled anesthetics in almost all cases, including while on CPB, as part of a balanced anesthetic technique and for their direct protective effects against ischemia/reperfusion myocardial injury.[74,75] Although isoflurane decreases blood pressure in neonates, infants, and children, the vasodilatory properties of isoflurane may improve overall myocardial contractility in contrast to the effects of halothane.[76] Despite improved cardiac reserve with isoflurane, the incidence of laryngospasm, coughing, and desaturation during induction of anesthesia limits its use as an induction agent in children with congenital heart defects.[77]

Desflurane has cardiorespiratory properties similar to those of isoflurane.[78] Its main advantage is low blood gas and tissue solubility, allowing for rapid equilibration between the inspired and alveolar concentrations and rapid decrease of alveolar concentrations during elimination.[79] This provides greater precision in drug dosing during the operative period and may make desflurane a more titratable adjunctive drug for pediatric cardiac anesthesia. The three main disadvantages of desflurane are potency, pungency, and negative inotropic effect.[80,81] Studies in normal infants and children suggest that 1 minimum alveolar concentration of desflurane requires concentrations of 8% to 10%.[82,83] Desflurane is also quite pungent, and, although its uptake is rapid, early experience with this drug for inhalation induction in children has reported a fairly high incidence of airway reactivity and laryngospasm.[83-85] Although its negative inotropic effect is significantly less potent than that of halothane, desflurane should not be used as the sole anesthetic in patients with significant cardiac dysfunction.[85]

Sevoflurane, our volatile anesthetic of choice, offers a more tolerable aroma without the magnitude of myocardial depression that accompanies halothane.[86] In addition, its blood gas solubility is nearly as low as that of desflurane. Hemodynamically, sevoflurane tends to produce some tachycardia, particularly in older children, and preserve systemic arterial pressure.[87] Reductions in heart rate and systemic arterial pressure are more modest in infants anesthetized with sevoflurane than in control subjects anesthetized with halothane, and the former exhibit echocardiographic evidence of normal contractility and cardiac index. This effect is particularly seen in children with trisomy 21.[88,89]

Children with complex CHD and limited cardiac reserve demand an anesthetic technique that provides hemodynamic stability. Inhalation anesthetics are less well tolerated as a sole primary anesthetic in patients who have limited cardiac reserve, especially after CPB. Fentanyl is an excellent induction and maintenance anesthetic for this group of patients. Low-to-moderate doses of this opioid can be supplemented with inhalation anesthetics. Adding low concentrations of inhalation anesthetics to smaller doses of opioids shortens or eliminates the need for postoperative mechanical ventilation while maintaining the advantage of intraoperative hemodynamic stability. Postoperative mechanical ventilation will be required when a high-dose (e.g., fentanyl > 20 μg/kg) opioid technique is used. The hemodynamic effects of fentanyl at a dose of 25 μg/kg with pancuronium given to infants in the postoperative period after operative repair of a congenital heart defect include no change in LAP, pulmonary artery pressure, PVR, and cardiac index and a small decrease in SVR and mean arterial pressure.[90] Because of its cardiovascular effects, pancuronium was an ideal neuromuscular blocking drug for pediatric heart surgery, but it is no longer available for clinical use. Therefore, either vecuronium or rocuronium are most often used. Larger doses of fentanyl at 50 to 75 μg/kg with rocuronium or vecuronium compared to doses of fentanyl at 50 to 75 μg/kg with pancuronium result in a slightly larger decrease in arterial blood pressure and heart rate in infants undergoing repair for complex congenital heart defects.[91] Despite the wide safety margin exhibited by this opioid, a selected population of infants and children with marginally compensated hemodynamic function sustained by endogenous catecholamines may manifest more extreme cardiovascular changes with these doses. Fentanyl also has been shown to block stimulus-induced pulmonary vasoconstriction and contributes to the stability of the pulmonary circulation in neonates after congenital diaphragmatic hernia repair.[92] Thus, the use of fentanyl may be extrapolated to the operating room, where stabilizing pulmonary vascular responsiveness in newborns and young infants with reactive pulmonary vascular beds is crucial to weaning from CPB and stabilizing shunt flow. Fentanyl in the 8 to 12 µg/kg dose range should provide sufficient analgesia, but still allow adequate ventilation efforts to allow for intraoperative extubation with stable hemodynamics during the procedure.

Children receiving sufentanil for induction of anesthesia as a single dose of 5 to 20 µg/kg have a stable preintubation period.[93,94] Intubation and other stimuli such as sternotomy do not produce clinically significant alterations in hemodynamics, although changes are more than with equipotent doses of fentanyl. The use of fentanyl as an infusion (1-2 µg/kg/h) produces fewer alterations in heart rate and blood pressure. This is particularly important in infants, in whom significant hemodynamic changes are poorly tolerated. For neonates with critical CHD, sufentanil anesthetic and postoperative infusion reduce morbidity after cardiac surgery when compared with a halothane anesthetic and routine morphine postoperatively.[95] The blunting of the stress response observed in this study probably accounted for the differences in morbidity; no comparison group representing a more typical dose of a phenylpiperidine opioid (e.g., fentanyl, 0-75 µg/kg) was included to permit conclusions as to whether such large opioid doses are optimal.

In contrast to other opioids, remifentanil, an ultra–short-acting opioid, offers the unique advantage of metabolism by nonspecific and tissue esterases, thereby limiting the potential for accumulation related to protracted elimination.[96] Remifentanil may provide advantages in the selected group of patients for whom the blunting of endogenous responses is desirable intraoperatively but potentially deleterious at the end of the procedure. A randomized controlled trial comparing equipotent doses of alfentanil and remifentanil for outpatient pediatric surgery revealed delayed emergence, requiring naloxone only in the alfentanil group.[97] In both adults and children, remifentanil is associated with qualitative hemodynamic changes similar to those with other opioids, a variable tendency to bradycardia, and a small decrease in arterial blood pressure.[98-101]

Because of the widespread use of the opioids for pediatric cardiac surgery and the availability of invasive monitoring, the pharmacokinetics and pharmacodynamics of these drugs have been well studied.[93,99] In general, the clinical pharmacology of fentanyl and sufentanil share the same age-related pharmacokinetic and pharmacodynamic features. For example, sufentanil has an increased clearance in patients 1 month to 12 years of age, comparable to adult clearance in adolescents (12-16 years of age), and a decreased clearance during the neonatal period (newborn to 1 month of age) (Table 78.7).[84,88] Furthermore, sequential sufentanil anesthetics in neonates with CHD show marked increases in clearance and elimination between the first week and the third or fourth week of life (Fig. 78.8).[101] The latter observation is most likely attributable to maturational changes in hepatic microsomal activity and improved hepatic blood flow from closure of the ductus venosus. The variability in clearance and elimination, coupled with limited cardiovascular reserve in the neonate during the first month of life, makes opioid dosing difficult in this age group.

TABLE 78.7 Sufentanil Pharmacokinetics in Pediatric Cardiovascular Patients

Age Group	$t_{1/2}\ \alpha$ (min)	$t_{1/2}\ \beta$ (min)	Clearance (mL/kg/min)	Vdss (L/kg)
1-30 days	23 ± 17	737 ± 346	6.7 ± 6.1	4.2 ± 1.0
1-24 months	16 ± 5	214 ± 41	18.1 ± 2.7	3.1 ± 1.0
2-12 years	20 ± 6	140 ± 30	16.9 ± 2.2	2.7 ± 0.5
12-18 years	20 ± 6	209 ± 23	13.1 ± 0.4	2.7 ± 0.5

All values are mean ± standard deviations (see Forbess et al.[386]).
$t_{1/2}\ \alpha$, Slow distribution half-life; $t_{1/2}\ \beta$, elimination half-life; *Vdss*, volume of distribution at steady state.

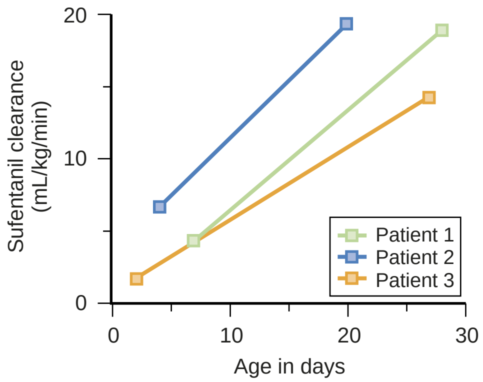

Fig. 78.8 Sequential sufentanil clearance during the first month of life in three neonates with congenital heart disease. Clearance of sufentanil increases above adult rates within the neonatal period. (Data from Greeley WJ, de Bruijn NP. Changes in sufentanil pharmacokinetics within the neonatal period. *Anesth Analg*. 1988;67:86–90.)

Careful titration of fentanyl 5 to 10 µg/kg or sufentanil 1 to 2 µg/kg or a continuous infusion technique provides the most reliable method of achieving hemodynamic stability and an accurate dose response. CPB, different institutional anesthetic practices, and individual patient differences influence pharmacokinetic and pharmacodynamic disposition of the opioids in ways that are not predictable. Even certain disease states such as TOF or pathophysiologic conditions such as increased intraabdominal pressure alter pharmacokinetic processes.[90,91]

Intraoperative use of methadone is an alternative pain control strategy introduced as an answer to counter acute tolerance to fentanyl infusions in the postoperative period. Adult data suggest that intraoperative use of methadone as the primary opioid in CPB cases significantly reduced the use of other opioids in the postoperative period, improved pain scores, and enhanced patient-perceived quality of pain management.[102] There is no pharmacokinetic data in children having CPB surgery, but available data show that the pharmacokinetic parameters in children and neonates are similar to those reported in adults, and that there is no clearance maturation with age.[103] For non-CPB cases, a dose of 0.2 mg/kg is suggested; we have used total doses of 0.3 to 0.4 mg/kg in CPB cases and extubated intraoperatively. Other strategies to address opioid tolerance include alternating opioid drugs, instituting opioid holidays, the addition of benzodiazepines on an as-needed basis, and the use of dexmedetomidine infusions.

Dexmedetomidine is an α_2-agonist approved by the U.S. Food and Drug Administration for sedation in adults. It has been used in pediatric anesthesia as part of a balanced technique preoperatively and intraoperatively for sedation, anxiolysis, and analgesia, and postoperatively for prevention of emergence delirium and sedation.[104] Dexmedetomidine has significant analgesic and antiinflammatory effects, attenuates the neuroendocrine response to surgery, and has no neurotoxic effects; it is a crucial adjunct to a balanced anesthetic as it reduces the need for other analgesics and hypnotics.[105-107]

The pharmacodynamic effects of dexmedetomidine when used as an infusion are generally well tolerated.[108] The clinical effects are predictable and usually insignificant with slight lowering of both heart rate and arterial blood pressure compared to baseline.[109] However, when administered as a rapid bolus, the first physiologic effect noted is hypertension along with heart rate slowing, lasting approximately 2 to 5 minutes before arterial blood pressure decreases.[110]

Dexmedetomidine demonstrates cardiac conduction effects, via both direct depression of the sinus and AV nodes in the heart, and decreased sympathetic tone in the locus coeruleus.[111] Clinically, this translates into a significant reduction of the incidence of junctional ectopic tachycardia post-CPB.[112] However, some studies and case reports, mostly in the adult literature, have documented clinically significant bradycardia, hypotension, and even asystole with its use. It is necessary to remain vigilant and titrate dexmedetomidine carefully. Dexmedetomidine should be used with particular caution in children at risk for bradycardia or sinus or AV node dysfunction, and possibly in patients who have had a heart transplant.[113] At our institution, dexmedetomidine is used in almost every case, with an infusion of 0.2 μg/kg/h in neonates and 0.5 μg/kg/h in all other cases initiated postinduction. The infusion is continued throughout the surgery and into the postoperative period. This practice is particularly helpful in patients that are extubated intraoperatively and we will often increase the dose to 1 to 2 μg/kg/h after extubation to keep the child calm for transport to the ICU.

Cardiopulmonary Bypass

DIFFERENCES BETWEEN ADULT AND PEDIATRIC CARDIOPULMONARY BYPASS

The physiologic effects of CPB on neonates, infants, and children are significantly different from the effects on adults (Table 78.8). During CPB, pediatric patients are exposed to biologic extremes not seen in adults, including deep hypothermia (18°C), hemodilution (threefold to fivefold greater dilution of circulating blood volume), low perfusion pressures (20-30 mm Hg), wide variation in pump flow rates (ranging from total circulatory arrest to 200 mL/kg/min), and differing blood pH management techniques (α-stat, pH-stat, or both sequentially). These parameters deviate far from normal physiology and affect preservation of normal organ function during and after CPB. In addition to these prominent changes, subtle variations in glucose supplementation, cannula placement, presence of aortopulmonary collaterals, and patient age affect organ function during CPB.

TABLE 78.8 Differences Between Adult and Pediatric Cardiopulmonary Bypass

Parameter	Adult	Pediatric
Hypothermic temperature	Rarely below 25°C -30°C	Commonly 15°C -20°C
Use of total circulatory arrest	Rare	Common
Pump prime		
Dilution effects on blood volume	25%-33%	150%-300%
Additional additives in pediatric primes		Blood, albumin
Perfusion pressures	50-80 mm Hg	20-50 mm Hg
Influence of α-stat versus pH-stat management strategy	Minimal at moderate hypothermia	Marked at deep hypothermia
Measured $PaCO_2$ differences	30-45 mm Hg	20-80 mm Hg
Glucose regulation		
Hypoglycemia	Rare—requires significant hepatic injury	Common—reduced hepatic glycogen stores
Hyperglycemia	Frequent—generally easily controlled with insulin	Less common—rebound hypoglycemia may occur

Adult patients are infrequently exposed to such biologic extremes; temperature is rarely lowered below 25°C, hemodilution is more moderate, perfusion pressure is generally maintained at 50 to 80 mm Hg, flow rates are maintained at 50 to 65 mL/kg/min, and pH management strategy is less consequential because of moderate hypothermic temperatures and rare use of circulatory arrest. Variables such as glucose supplementation rarely pose a problem in adult patients owing to large hepatic glycogen stores. Venous and arterial cannulas are less deforming of the atria and aorta, and their placement is more predictable. Although superficially similar, the conduct of CPB in children is considerably different from that in adults. Marked physiologic differences in the response to CPB in children can occur. Additionally, several modifiable intraoperative factors can influence neuropsychologic morbidity (Box 78.3).

Volume of Priming Solutions

The priming solutions used in pediatric CPB take on great importance because of the disproportionately large priming volume–to–blood volume ratio in children. In adults, the priming volume is equivalent to 25% to 33% of the patient's blood volume, whereas in neonates and infants the priming volume may exceed the patient's blood volume by 200%. With contemporary low-volume bypass circuits (e.g., small volume oxygenators, smaller tubing), priming volume is not more than one blood volume in a small neonate. Care must be taken, therefore, to achieve a physiologically balanced priming solution and limit the volume as much as

BOX 78.3 Central Nervous System Injury and Potential Modifiable Intraoperative Factors

Air or particulate embolus
Rate and depth of core cooling (if used)
Deep hypothermic circulatory arrest (if used)
Reperfusion injury and inflammation
Rate of core rewarming/hyperthermia
Hyperglycemia

pH management during cardiopulmonary bypass
Hematocrit management during cardiopulmonary bypass

possible. Most pediatric priming solutions, however, have quite variable levels of electrolytes, calcium, glucose, and lactate. Electrolytes, glucose, and lactate levels may be quite high if the solution includes large amounts of banked blood or quite low if a minimal amount of banked blood is added. Calcium levels are generally very low in pediatric priming solutions; this may contribute to the rapid slowing of the heart with the initiation of bypass.

The main constituents of the priming solution include crystalloid, colloid, and, if necessary, banked blood to maintain a temperature-appropriate hematocrit. Other potential supplements are fresh frozen plasma, mannitol, a buffer (sodium bicarbonate or trishydroxymethylaminomethane [THAM]), and steroids. Low concentrations of plasma proteins have been shown experimentally to impair lymphatic flow and alter pulmonary function by increasing capillary leak.[114] Although adding albumin to the pump prime has not been shown to alter outcome in adults during CPB, one study suggested that maintaining normal colloid osmotic pressure may improve survival in infants undergoing CPB.[115,116]

Whole blood, if available, is an alternative to adding both packed RBCs and fresh frozen plasma. Blood cells are added to the prime solution to maintain a postdilutional hematocrit of at least 20% to 25% (usually higher in patients with cyanotic CHD), and plasma restores levels of procoagulants. Low-volume bypass circuits enable perfusionists and anesthesiologists to share a single unit of whole blood, thereby limiting the donor.

The addition of any blood products will cause a much higher glucose load in the priming solution. Hyperglycemia may increase the risk for neurologic injury if brain ischemia occurs. Mannitol is added to promote an osmotic diuresis and scavenge O_2 free radicals from the circulation. Steroids are added to stabilize membranes and produce the theoretic advantage of reducing ion shifts during periods of ischemia, attenuating inflammation caused by CPB, decreasing low cardiac output states, and improving fluid balance in the postoperative period. Steroids, however, may raise glucose levels, which can be detrimental if there is a period of cerebral ischemia, and may suppress immune function. Steroids remain a controversial additive in priming solutions. Recent retrospective data suggest negative effects with its use and an association with decreased survival in neonates having the Norwood procedure.[117] A number of prospective studies are ongoing to address the role of steroids in pediatric cardiac surgery.

Temperature

Hypothermic CPB is used to preserve organ function during cardiac surgery. Three distinct methods of CPB are used: moderate hypothermia (25°-32°C), deep hypothermia (18°C), and DHCA. The choice of method of bypass is based on the required surgical conditions, patient size, type of operation, and potential physiologic impact on the patient.

Moderate hypothermic CPB is the principal method of bypass employed for older children and adolescents. In these patients, venous cannulas are less obtrusive and the heart can easily accommodate superior and inferior vena cava cannulation. Bicaval cannulation reduces right atrial blood return and improves the surgeon's ability to visualize intracardiac anatomy. Moderate hypothermia may also be chosen for less demanding cardiac repairs, such as an ASD or uncomplicated VSD. Most surgeons are willing to cannulate the inferior and superior venae cavae in neonates and infants. In these patients, however, this approach is technically more difficult and likely to induce brief periods of hemodynamic instability. Additionally, the pliability of the venae cavae and the rigidity of the cannulas may result in caval obstruction, impaired venous drainage, and elevated venous pressure in the mesenteric and cerebral circulation.

Deep hypothermic CPB is generally reserved for neonates and infants requiring complex cardiac repair. However, certain older children with complex cardiac disease or severe aortic arch disease benefit from deep hypothermic temperatures. For the most part, deep hypothermia is selected to allow the surgeon to operate under conditions of low-flow CPB or total circulatory arrest. Low pump flows (50 mL/kg/min) improve the operating conditions for the surgeon by providing a nearly bloodless field. DHCA allows the surgeon to remove the atrial or aortic cannula. If this technique is used, surgical repair is more precise because of the bloodless and cannula-free operative field. Arresting the circulation, even at deep hypothermic temperatures, introduces the concern of how well deep hypothermia preserves organ function, with the brain being at greatest risk. Three-region perfusion techniques may be an option to deep hypothermic CPB, but further studies are needed to assess feasibility and outcomes of this newer strategy.

Hemodilution

Hemodilution is used during CPB to decrease homologous blood use and improve microcirculatory flow by reducing blood viscosity during periods of hypothermia. Although hemoconcentrated blood has an improved O_2-carrying capacity, its viscosity reduces efficient flow through the microcirculation. With hypothermic temperatures, blood viscosity increases significantly and flow decreases. Hypothermia, coupled with the nonpulsatile flow of CPB, impairs blood flow through the microcirculation. Blood sludging, small vessel occlusion, and multiple areas of tissue hypoperfusion may result. Therefore, hemodilution is an important consideration during hypothermic CPB.

The appropriate level of hemodilution for a given hypothermic temperature, however, is not well defined. Further, hemodilution reduces perfusion pressure; increases CBF, thereby potentially increasing the microembolic load to the brain; and reduces the O_2-carrying capacity of blood.[118] Using an animal model, one group of investigators found that extreme hemodilution to a hematocrit less than 10% resulted in inadequate O_2 delivery, but with higher hematocrit levels of 30%, there was improved cerebral recovery after DHCA.[119] Jonas and colleagues[120] confirmed these findings in a randomized trial using two hemodilution protocols (20% vs. 30% hematocrit) in infants younger than 9 months of age. In the short term, the group with lower hematocrit values had lower nadirs of cardiac index, higher serum lactate levels 1 hour after CPB, and a greater increase in total body water on the first postoperative day. At 1 year of age, mental development index scores were similar but psychomotor development index scores were significantly lower in the group with lower hematocrit values. Also, infants in this group had psychomotor development scores that were 2 standard deviations below the mean. Because RBCs serve as the major reservoir of O_2 during circulatory arrest, especially during rewarming, hematocrit values closer to 30% are generally preferred for deep hypothermia when this technique is contemplated. Currently, most centers maintain hematocrit levels approximately 25% to 30% during CPB, enhancing O_2 delivery to vital organs such as the brain. Cerebral O_2 delivery is an especially important consideration because cerebral autoregulation is impaired at deep hypothermic temperatures and after DHCA.

To achieve a hematocrit level of 25% to 30% in neonates and infants, banked blood should be added to the priming solution. The mixed hematocrit level on CPB (the hematocrit level of the total priming volume plus the patient's blood volume) can be calculated by the following formula:

$$\mathrm{Hct_{CPB}} = \mathrm{BV_{pt}} \times \mathrm{HCT_{pt}} / \mathrm{BV_{pt}} + \mathrm{TPV}$$

where $\mathrm{Hct_{CPB}}$ is the mixed hematocrit (TPV + BVpt), $\mathrm{BV_{pt}}$ is the patient's blood volume (weight in kilograms × estimated blood volume in milliliters per kilogram), TPV is the total priming volume, and $\mathrm{Hct_{pt}}$ is the starting hematocrit level of the patient. This calculation allows an estimate of the hematocrit level of the patient using an asanguinous priming solution and is therefore useful for older children and adolescents. In neonates and infants, the perfusionist must add blood to the pump prime to achieve a desired hematocrit level during hypothermic CPB. The following formula estimates the amount of packed RBCs in milliliters that must be added to the prime volume to achieve this hematocrit level:

$$\begin{aligned}\text{Added RBCs (mL)} &= (\mathrm{BV_{pt}} + \mathrm{TPV})\,(\mathrm{Hct_{desired}}) \\ &\quad - (\mathrm{BV_{pt}})\,(\mathrm{Hct_{pt}})\end{aligned}$$

where $\mathrm{BV_{pt}}$ is the patient's blood volume, TPV is the total priming volume, $\mathrm{Hct_{desired}}$ is the desired hematocrit level on CPB, and $\mathrm{Hct_{pt}}$ is the starting hematocrit level of the patient.

Like in adults, the optimal hematocrit level after weaning from CPB is not clear for pediatric patients. Decisions concerning post-CPB hematocrit levels are made based on the patient's post-repair function and anatomy. Neonates, patients with residual hypoxemia, and those with moderate-to-severe myocardial dysfunction benefit from the improved O_2-carrying capacity of hematocrit levels of 40% or higher. Patients with a physiologic correction and excellent myocardial function may tolerate hematocrit levels of 25% to 30%.[121] In children with mild-to-moderate myocardial dysfunction, accepting hematocrit values between these levels seems prudent. Therefore, in patients with physiologic correction, moderately good ventricular function, and hemodynamic stability, the risks associated with blood and blood product transfusion should be strongly considered during the immediate postbypass period.

BLOOD GAS MANAGEMENT

The theoretic benefit of α-stat versus pH-stat blood gas management during hypothermic CPB has been a topic of great debate. Although the pH-stat strategy may not be optimal for adults in whom the principal risk for brain injury is microembolism, this risk is thought to be lower in infants because of the lack of atherosclerotic disease. With pH-stat management, the addition of CO_2 to the inspired gas mixture during cooling on CPB increases CBF and may improve cerebral tissue oxygenation and outcomes.

The controversial issue of pH management during CPB has been addressed in a large study from Boston Children's Hospital. In this study, infants younger than 9 months of age were randomized to α-stat versus pH-stat during deep hypothermic CPB with excellent long-term follow-up.[122,123] Neurodevelopmental outcomes were evaluated in infants undergoing biventricular repair for a variety of cardiac defects when younger than 9 months of age. The short-term benefits identified with the pH-stat strategy included a trend toward less postoperative morbidity and shorter recovery time to first electroencephalographic activity. In patients with TGA, there was a shorter duration of intubation and ICU stay in patients.[122] However, the use of either the α-stat or pH-stat strategies was not consistently related to either improved or impaired neurodevelopmental outcomes at 2- and 4-year follow-up.[123]

INITIATION OF CARDIOPULMONARY BYPASS

Arterial and venous cannula placed in the heart before initiating CPB may result in significant problems in the peribypass period. A malpositioned venous cannula has the potential for vena cava obstruction. The problems of venous obstruction are magnified during CPB in the neonate because arterial pressures are normally low (20-40 mm Hg), and large, relatively stiff cannulas easily distort these very pliable venous vessels.[114,116] A cannula in the inferior vena cava may obstruct venous return from the splanchnic bed, resulting in ascites from increased hydrostatic pressure or directly reduced perfusion pressure across the mesenteric, renal, and hepatic vascular beds. Significant renal, hepatic, and gastrointestinal dysfunction may ensue and should be anticipated in the young infant with unexplained ascites. Similar cannulation problems may result in superior vena cava obstruction. This condition may be more ominous during bypass. Under these circumstances, three problems may ensue: (1) cerebral edema, (2) a reduction in regional or global CBF, and (3) reduced proportion of pump flow reaching the cerebral circulation, causing inefficient brain cooling.

In the operating room, superior vena cava pressures via an internal jugular catheter should be monitored by examining the patient's head for signs of suffusion after initiating bypass. Discussions with the perfusionist regarding adequacy of venous return and large cooling gradients between the upper and lower body should alert the anesthesiologist and the surgeon to potential venous cannulae problems. Patients with anomalies of the large systemic veins (persistent left superior vena cava or azygous continuation of an interrupted inferior vena cava) are at particular risk for problems with venous cannulation and drainage.

Problems with aortic cannula placement can occur. The aortic cannula may slip beyond the takeoff of the innominate artery, with blood therefore selectively flowing to the right side of the cerebral circulation. Also, the position of the tip of the cannula may promote preferential flow down the aorta or induce a Venturi effect to steal flow from the cerebral circulation. This problem has been confirmed during CBF monitoring by the appearance of large discrepancies in flow between the right and left hemispheres after initiating CPB. The presence of large aortic-to-pulmonary collaterals, such as a large PDA, also may divert blood to the pulmonary circulation from the systemic circulation, thereby reducing CBF and the efficiency of brain cooling during CPB. The surgeon should gain control of the ductus either before or immediately after instituting CPB to eliminate this problem and, if possible, large aortopulmonary collaterals should be embolized in the cardiac catheterization laboratory before the operative procedure. Neonates with significant aortic arch abnormalities (e.g., aortic atresia, interrupted aortic arch) may require radical modifications of cannulation techniques, such as placing the arterial cannula in the main pulmonary artery and temporarily occluding the branch pulmonary arteries to perfuse the body via the PDA or even dual arterial cannulation of both the ascending aorta and main pulmonary artery. Such adaptations require careful vigilance to ensure effective, thorough perfusion and cooling of vital organs.

Once the aortic and venous cannulas are positioned and connected to the arterial and venous limb of the extracorporeal circuit, bypass is initiated. The arterial pump is slowly started, and, once forward flow is ensured, venous blood is drained into the oxygenator. Pump flow rate is gradually increased until full circulatory support is achieved. If venous return is diminished, arterial line pressure is high, or mean arterial pressure is excessive, pump flow rates must be reduced. High line pressure and inadequate venous return are usually caused by malposition or kinking of the arterial and venous cannulae, respectively. The rate at which venous blood is drained from the patient is determined by the height difference between the patient and the oxygenator inlet and the diameter of the venous cannula and line tubing. Venous drainage can be increased by using vacuum-assisted drainage under certain circumstances.

In neonates and infants, deep hypothermia is commonly used. For this reason, the pump prime is kept cold (18°-22°C). When the cold perfusate contacts the myocardium during the institution of CPB, heart rate slows immediately and contraction is impaired. The contribution of total blood flow pumped by the infant's heart rapidly diminishes. Therefore, to sustain adequate systemic perfusion at or near normothermic temperatures, the arterial pump must reach full flows quickly.

CPB is initiated in neonates and infants by beginning the arterial pump flow first. Once aortic flow is ensured, the venous line is unclamped and blood is siphoned out of the RA into the inlet of the oxygenator. Flowing before unclamping the venous line prevents the potential problem of exsanguination if aortic dissection or misplacement of the aortic cannula occurs. Neonates and infants have a low blood volume–to–priming volume ratio, and intravascular volume falls precipitously if the venous drainage precedes aortic inflow. Once the aortic cannula position is verified, pump flow rates are rapidly increased to maintain effective systemic perfusion. Because coronary artery disease is rarely a consideration, the myocardium should cool evenly unless distortion caused by the cannulas compromises the coronary arteries. When a cold prime is used, caution must be exercised in using the pump to infuse volume before initiating CPB. Infusion of cold perfusate may result in bradycardia and impaired cardiac contractility before the surgeon is prepared to initiate CPB.

Once CPB is initiated, appropriate circuit connections, myocardial perfusion, and optimal cardiac decompression should be confirmed. Ineffective venous drainage can rapidly result in ventricular distention. This is especially true in infants and neonates, in whom ventricular compliance is low and the heart is relatively intolerant of excessive preload augmentation. If ventricular distention occurs, pump flow must be reduced and the venous cannula repositioned. Alternatively, the heart may be decompressed by placing a cardiotomy suction catheter or small vent in the appropriate chamber.

PUMP FLOW RATES

Recommendations for optimal pump flow rates for children have historically been based both on the patient's body mass and on evidence of efficient organ perfusion as determined by arterial blood gases, acid-base balance, and whole-body O_2 consumption during CPB.[124] At hypothermic temperatures, metabolism is reduced, and CPB flow rates can therefore be reduced and still meet or exceed the tissue's metabolic needs (see the discussion of low-flow CPB in the following section).

SPECIAL TECHNIQUES

Deep Hypothermic Circulatory Arrest

A certain subset of neonates, infants, and children with CHD require extensive repair of complex congenital heart defects using DHCA. This technique facilitates precise surgical repair under optimal conditions, with no blood or cannulae in the operative field and providing maximal organ protection and often resulting in shortened total CPB time. The scientific rationale for the use of deep hypothermic temperatures rests primarily on a temperature-mediated reduction of metabolism. Whole-body and cerebral O_2 consumption during induced hypothermia decreases the metabolic rate for O_2 by a factor of 2 to 2.5 for every 10°C reduction in temperature.[125] These results are consistent with in-vitro models, which relate temperature reduction to a decrease in the rate constant of chemical reactions, as originally described by Arrhenius using the equation $k = Ae - RT$. The reduction in O_2 supply during deep hypothermic low-flow CPB is associated with preferential increases in vital organ perfusion (e.g., to the brain) and increased extraction of O_2.[126] Therefore, to some extent, deep hypothermic low-flow CPB

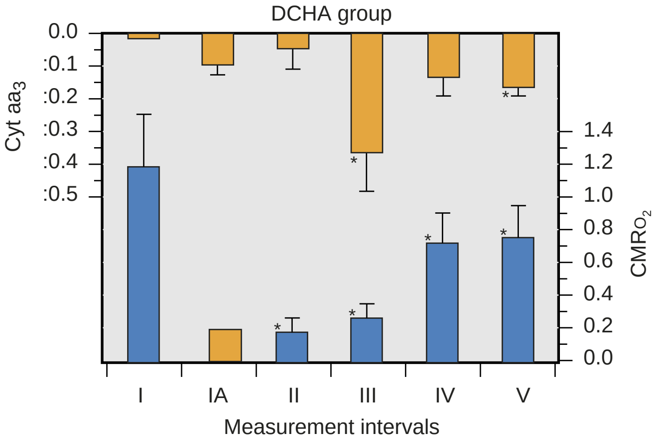

Fig. 78.9 Bar graph of variations in cytochrome oxidase *(cyt aa_3)* near-infrared spectroscopic signals and cerebral metabolic rate for oxygen *(CMRO_2)* in subjects with deep hypothermic circulatory arrest *(DHCA)*. Each point of cyt aa_3 represents mean ± SE in six subjects; CMRO_2 values are mean ± SD. Negative values in cyt aa_3 represent relative decreases in quantity of oxidized enzyme. *CMRO_2 and cyt aa_3 are significantly different from control, $P \pm .05$.

exerts a protective effect by reducing the metabolic rate for O_2, promoting preferential organ perfusion, and increasing tissue O_2 extraction.

The duration of the safe period for DHCA has not clearly been delineated.[127] Although all organ systems are at risk for the development of ischemic and reperfusion injury, as manifested by lactate and pyruvate production during DHCA, the brain appears to be the most sensitive to and the least tolerant of these effects. Brainstem and cortical evoked potentials as well as processed electroencephalographs are altered after DHCA.[127-129] The abnormalities in evoked potentials appear to be related to the duration of DHCA and are attributed to altered metabolism. During reperfusion after the arrest period, CBF and metabolism remain depressed in neonates and small infants (Fig. 78.9; also see Fig. 78.6).[70] Importantly, during the use of these extremes of temperature, autoregulation is lost and cerebral perfusion becomes highly dependent on the extracorporeal perfusion and presumably postbypass hemodynamic performance.

The potentially deleterious effects of prolonged DHCA in infants and neonates are well described. In general, it is agreed that very prolonged periods of uninterrupted DHCA may have adverse neurologic outcomes. However, considerable disagreement exists if a “safe” period of DHCA exists and whether patient-specific, procedure-specific, or postoperative management strategies may attenuate or promote CNS damage from DHCA. Cases have been reported of detrimental effects of DHCA on a variety of outcomes regarding the CNS, while others have described an inconsistent effect or no effect.[122,130,131] Three issues have become clear over time: (1) the effects of short durations of DHCA are inconsistently related to adverse outcomes, (2) the effect of DHCA is not a linear phenomenon, and (3) the effects are most likely modified by other patient-related, preoperative, and postoperative factors.[131-133] A large-scale study of 549 subjects undergoing the Norwood stage 1 procedure with DHCA found duration of greater than 45 minutes to be a risk factor for 30-day mortality.[134]

Regional Cerebral Perfusion

Some surgeons have developed innovative and challenging strategies to provide continuous cerebral perfusion during complex reconstruction of the aortic arch or intracardiac repair to avoid or minimize the use of DHCA. However, avoiding DHCA, the duration of CPB is necessarily lengthened, and longer durations of CPB have been shown to adversely affect both short- and long-term outcomes.[51,52] The relative risks and benefits of longer CPB versus less (or no) DHCA remain a subject of continued controversy. In efforts to study this newer strategy, two recent studies have evaluated the technique of regional cerebral perfusion. In one non-randomized study, Wypij and colleagues[135] followed 29 infants who underwent a stage 1 palliation, 9 of whom received regional cerebral perfusion at 30 to 40 mL/kg/min. The authors reported no difference in mental or psychomotor developmental indices at 1 year of age between the regional cerebral perfusion group and those who received DHCA as a primary strategy. A larger randomized trial of DHCA with or without regional cerebral perfusion at 20 mL/kg/min in patients with a functional single ventricle included 77 patients with similar survival to hospital discharge (88%) and at 1-year follow-up (75%).[136] No significant difference was seen in either the psychomotor development index or the mental development index scores between the two groups at any time points, although the scores tended to be lower in the regional cerebral perfusion group.

A further innovation to the previously described technique is a three-region perfusion strategy for aortic arch reconstruction in the Norwood procedure. This strategy involves direct perfusion of the coronaries via a proximal aortic cannula, splanchnic beds via a distal thoracic aorta cannula, and cerebral perfusion via an innominate cannula. The arch repair occurs from distal to proximal at warmer patient temperatures and with a beating heart. This theoretically provides the potential for decreased coronary and splanchnic ischemic times, decreasing the risk of cardiac dysfunction and abdominal organ damage, and mitigating the negative hypothermic effects on the hematological system.[2,3] Larger, long-term studies are needed to assess the efficacy of this technique in improving cardiovascular, renal, and other outcomes.

Glucose Regulation

The detrimental effects of hyperglycemia during complete, incomplete, and focal cerebral ischemia are well demonstrated.[137,138] The role of glucose in potentiating cerebral injury appears to rest on two factors: adenosine triphosphate (ATP) usage and lactic acidosis.[139,140] The anaerobic metabolism of glucose requires phosphorylation and the expenditure of two molecules of ATP before ATP production can occur. This initial ATP expenditure may result in a rapid depletion of ATP and may explain why hyperglycemia worsens neurologic injury. Lactic acidosis is also important in glucose-augmented cerebral injury, though its role may be as a glycolytic enzyme inhibitor: lactate slows anaerobic ATP production by inhibiting glycolysis immediately after ATP is consumed in the phosphorylation of glucose.[141]

Although the detrimental effects of hyperglycemia during ischemia are clear, very little evidence supports a relationship between a worsening neurologic outcome and hyperglycemia during CPB or DHCA in children. A review of acquired neurologic lesions in patients undergoing the Norwood stage 1 procedure for HLHS suggested hyperglycemia as a significant associated finding in patients with extensive cerebral necrosis or intraventricular hemorrhage. A host of other potentially damaging factors (e.g., periods of hypoxia, low diastolic and systolic pressure, thrombocytopenia) were statistically associated with the observed neuropathology.[142] Whether glucose directly contributes to neurologic injury or merely serves as a marker for a high-risk population that ultimately suffers neurologic insult as a result of other factors is not clear.

Hypoglycemia is also a frequent concern in neonates during the perioperative period. Reduced hepatic gluconeogenesis coupled with decreased glycogen stores places the newborn at increased risk for hypoglycemic events. In newborns with CHD, reduced systemic perfusion (e.g., critical coarctation, HLHS, critical aortic stenosis) may result in worsening hepatic biosynthesis, further impairing glucose production. These patients may be fully dependent on exogenous glucose; therefore, it is not uncommon for them to require 20% to 30% dextrose infusions to maintain euglycemia in the prebypass period. Older children are not immune to hypoglycemic events and are therefore susceptible to hypoglycemia-induced neurologic injury. Patients with low cardiac output states (cardiomyopathies, pre-transplant patients, critically ill postoperative patients) requiring reoperation and when on substantial inotropic support are at high risk for reduced glycogen stores and intraoperative hypoglycemia.[143]

The impact of hypoglycemia during CPB is further complicated by the consequences of hypothermia, CO_2 management, and other factors that may modify normal cerebrovascular responses during bypass. In a dog model, insulin-induced hypoglycemia to 30 mg/dL did not alter the electroencephalographic findings. However, after 10 minutes of hypocapnic hypoglycemia, the electroencephalogram became flat.[144] The loss of electroencephalographic activity from hypoglycemia alone does not normally occur above glucose levels of 8 mg/dL.[145]

During deep hypothermic CPB and DHCA, CBF and metabolism are altered. The additive effect of hypoglycemia, even if mild, may cause alterations in cerebral autoregulation and culminate in increased cortical injury.[142] The common practice of using hyperventilation to reduce PVR in neonates and infants during weaning from CPB and in the early postbypass period can further exacerbate hypoglycemic injury. Glucose monitoring and rigid maintenance of euglycemia are an important part of CPB management in the patient with CHD.

Renal Effects

After CPB, the combined effects of hypothermia, nonpulsatile perfusion, and reduced mean arterial pressure cause release of angiotensin, renin, catecholamines, and antidiuretic hormones.[146-148] These circulating hormones promote renal vasoconstriction and reduce renal blood flow. However, despite the negative impact of CPB on renal function, low-flow, low-pressure, nonpulsatile perfusion has not been linked with postoperative renal dysfunction (Table 78.9).[147] The factors that best correlate with postoperative renal dysfunction are preoperative renal dysfunction and profound reductions in post-CPB cardiac output. Preoperative factors include primary renal disease, low cardiac output, and dye-related renal injury after cardiac catheterization.[148]

TABLE 78.9 Sequelae of Pediatric Cardiopulmonary Bypass

End-Organ Injury	Cause and Signs
Renal injury	Organ immaturity, preexisting renal disease Post–cardiopulmonary bypass low cardiac output, use of DHCA Renal dysfunction characterized by reduced GFR and ATN
Pulmonary injury	Endothelial injury, increased capillary leak, complement activation, and leukocyte degranulation Pulmonary dysfunction characterized by reduced compliance, reduced FRC, and increased A-a gradient
Cerebral injury after DHCA	Loss of autoregulation, suppressed metabolism and cerebral blood flow, cellular acidosis, and cerebral vasoparesis CNS dysfunction characterized by seizures, reduced developmental quotients, choreoathetosis, learning disabilities, behavioral abnormalities

A-a, Alveolar-arterial; ATN, acute tubular necrosis; *CNS,* central nervous system; *DHCA,* deep hypothermic circulatory arrest; *FRC,* functional residual capacity; *GFR,* glomerular filtration rate.

Acute kidney injury after pediatric cardiac surgery has an incidence between 20% to 60% depending on criteria used.[149] Multiple causative factors are involved, and the final common result is oliguria and an increased serum creatinine. Diuretics have been the mainstay of promoting urine flow after pediatric CPB. Furosemide in a dose of 1 to 2 mg/kg or ethacrynic acid 1 mg/kg every 4 to 6 hours, or both, induces diuresis and may reverse renal cortical ischemia associated with CPB. After DHCA, a 24-hour period of oliguria or anuria can occur that resolves over the next 12- to 24-hour period. The use of diuretics is effective only after spontaneous urine output has been initiated in these patients.

Glomerular filtration rate, creatinine clearance, and medullary concentrating ability are substantially reduced in neonates and young infants. Therefore, the use of CPB in these patients results in greater fluid retention than is typically seen in older children and adult patients. The net result may be increased total body water, increased organ weight (e.g., lungs, heart), and greater difficulty with postoperative weaning from ventilatory support. The use of ultrafiltration during rewarming or after CPB is effective in reducing total body water, limiting the damaging effects of CPB, and decreasing the postoperative ventilation period.[150,151]

Pulmonary Effects

Cardioplegia protects the heart, but no parallel protection is afforded to the lungs during bypass. Pulmonary dysfunction is common after CPB, and its pathogenesis is poorly understood (see Table 78.9). In the broadest terms, lung injury is mediated in one of two ways: first, by an inflammatory response resulting from leukocyte and complement activation and, second, by a mechanical effect culminating in surfactant loss, atelectasis with resultant ventilation-perfusion mismatch, loss of lung volumes, and altered mechanics of breathing.

Pulmonary function after CPB is characterized by reduced static and dynamic compliance, reduced functional residual capacity, surfactant deficiency, and an increased A-a gradient.[152,153] Atelectasis and increased capillary leak due to hemodilution and hypothermic CPB are the most likely causes. Hemodilution reduces circulating plasma proteins, reducing intravascular oncotic pressure, and favors water extravasation into the extravascular space. Hypothermic CPB causes complement activation and leukocyte degranulation.[154] Leukocytes and complement are important in causing capillary-alveolar membrane injury and microvascular dysfunction through platelet plugging and release of mediators, which increase PVR. The technique of MUF is highly effective in reducing lung water and pulmonary morbidity during the postoperative period.

STRESS RESPONSE AND CARDIOPULMONARY BYPASS

The release of a large number of metabolic and hormonal substances, including catecholamines, cortisol, growth hormone, prostaglandins, complement, glucose, insulin, endorphins, and other substances, characterizes the stress response during hypothermic CPB.[9,155] The likely causes of the elaboration of these substances include contact of blood with the nonendothelialized surface of the pump tubing and oxygenator, nonpulsatile flow, low perfusion pressure, hemodilution, hypothermia, and light anesthesia depth. Other factors that may contribute to elevations of stress hormones include delayed renal and hepatic clearance during hypothermic CPB, myocardial injury, and exclusion of the pulmonary circulation from bypass. The lung is responsible for metabolizing and clearing many of these stress hormones. The stress response generally peaks during rewarming from CPB. Strong evidence indicates that the stress response can be blunted by increasing the depth of anesthesia.[9,155]

The stress response in return can mediate undesirable effects such as myocardial damage (catecholamines), systemic and pulmonary hypertension (catecholamines, prostaglandins), pulmonary endothelial damage (complement, prostaglandins), and pulmonary vascular reactivity (thromboxane). The benefits of controlling the stress response with fentanyl in premature infants undergoing PDA ligation and with sufentanil in neonates with complex CHD have been demonstrated.[95,156] Although blunting the stress response seems warranted, additional evidence suggests that the newborn stress response, especially the endogenous release of catecholamines, may be an adaptive metabolic response necessary for survival at birth.[157] Thus, the complete elimination of an adaptive stress response may not be desirable. To what extent acutely ill neonates with CHD depend on the stress response for maintaining hemodynamic stability is currently unknown.

A depth of anesthesia adequate to attenuate the stress response should be used, but to attempt to block the response altogether is likely not necessary. Acceptable anesthesia during CPB may be best accomplished by the continuous administration of an inhaled anesthetic via a vaporizer connected to the pump oxygenator, dexmedetomidine infusion, careful titration of incremental doses of opioids, or the precise administration of an opioid or opioid and benzodiazepine by a continuous infusion technique. Primary opioid anesthetic techniques result in reduced stress hormone release and decreased postoperative metabolic acidosis and lactate production compared with halothane anesthesia and may therefore be a preferred technique in complex CHD.[95] If an adequate depth of anesthesia is accomplished by the administration of excessively large doses of opioids (e.g., fentanyl or sufentanil), postoperative mechanical ventilation will be necessary. By contrast, residual levels of inhaled anesthetics (e.g., halothane or isoflurane) can produce transient myocardial depression at the termination of CPB, complicating separation from CPB. Because of the improved surgical techniques coupled with the reduced morbidity of CPB, the use of high doses of an opioid anesthetic is infrequent in current practice.

DISCONTINUATION OF CARDIOPULMONARY BYPASS

In separating the patient from CPB, blood volume is assessed by direct visualization of the heart and monitoring right atrial or left atrial filling pressures. When filling pressures are adequate, the patient is fully warmed, acid-base status is normalized, heart rate is adequate, and sinus rhythm has been achieved, the venous drainage is stopped and the patient can be weaned from bypass. The arterial cannula is left in place so that a slow infusion of residual pump blood can be used to optimize filling pressures. Myocardial function is assessed by direct cardiac visualization and a transthoracic left or right atrial catheter, by a percutaneous internal jugular catheter, or by the use of intraoperative echocardiography. Pulse oximetry also can be used to assess the adequacy of cardiac output.[158] Low systemic arterial saturation or the inability of the oximeter probe to register a pulse may be a sign of very low output and high systemic resistance.[159]

After the repair of complex congenital heart defects, the anesthesiologist and surgeon may have difficulty separating patients from CPB. Under these circumstances, a diagnosis must be made and includes (1) an inadequate surgical result with a residual defect requiring repair, (2) pulmonary artery hypertension, and (3) right or left ventricular dysfunction.

Two general approaches are customarily used, either independently or in conjunction. An intraoperative “cardiac catheterization” can be performed to assess isolated pressure measurements from the various great vessels and chambers of the heart (i.e., catheter pullback measurements or direct needle puncture to evaluate residual pressure gradients across repaired valves, sites of stenosis and conduits, and O_2 saturation data to examine for residual shunts).[160] Alternatively, echo-Doppler imaging may be used to provide an intraoperative image of structural or functional abnormalities to assist in the evaluation of the postoperative cardiac repair.[7,161] If structural abnormalities are found, the patient can be placed back on CPB and residual defects can be repaired before the patient leaves

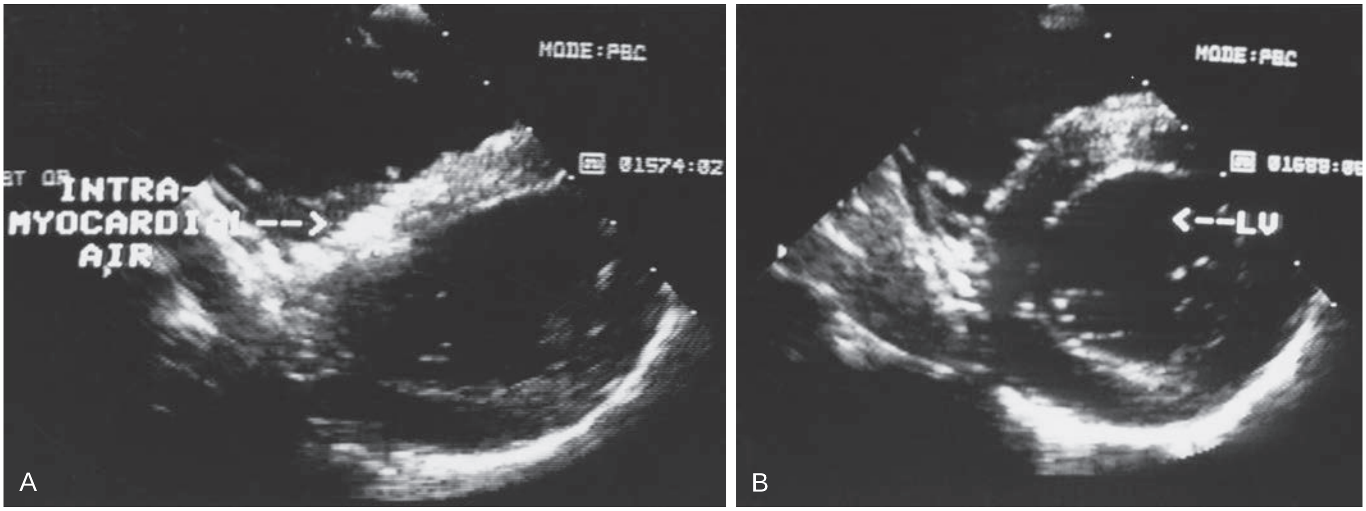

Fig. 78.10 (A) Two-dimensional echocardiogram in the short-axis view across the ventricles demonstrating the presence of intramyocardial air *(arrow)* in the ventricular septum and right ventricular wall. The intramyocardial air appears as a dense, "snowy" echogenic area. Note the associated wall motion abnormality appearing as flattening of the ventricular septum. (B) The patient was treated with phenylephrine, increasing systemic and coronary perfusion pressure, resulting in clearance of the air, normalization of the echogenic density, and restoration of normal left ventricular *(LV)* wall motion and configuration.

the operating room. Leaving the operating room with a significant residual structural defect adversely affects survival and increases patient morbidity (see Fig. 78.5).[7,161] Echo-Doppler imaging can rapidly identify right and left ventricular dysfunction and suggest the presence of pulmonary artery hypertension. In addition, echo-Doppler imaging can identify regional wall motion abnormalities caused by ischemia or intramyocardial air that will direct specific pharmacologic therapy and provide a means of assessing the results of these interventions (Fig. 78.10).[162]

ULTRAFILTRATION

Institution of CPB in neonates, infants, and young children results in a profound proinflammatory response and significant hemodilution. This may contribute to post-CPB morbidity and mortality resulting from poor organ function. The organ systems most affected by this are the heart, lungs, and brain. Although contact between the patient's blood and the foreign surface of the bypass circuit is a potent stimulus to trigger the inflammatory cascade, other factors including ischemia, profound hypothermia, rewarming, and surgical trauma are also important in its genesis. These inflammatory mediators include complement anaphylatoxins, vasoactive amines, and cytokines (e.g., tumor necrosis factor-α [TNF-α]) that lead to an increase in vascular permeability.[163] Hemodilution occurs at the onset of CPB despite the use of physiologically balanced priming solutions that include blood, crystalloid, albumin, and buffer and smaller volume circuits. Hemodilution may, however, be advantageous in patients in whom the surgery is performed under hypothermic conditions ranging from mild hypothermia to DHCA. Initiation of CPB will change the viscoelastic properties of blood, and these changes have been shown to continue into the post-CPB period.[164] Although the mode of perfusion, cardiotomy suction, arterial roller pump type, and shear forces of the CPB circuit are important, it is the temperature and hematocrit of the blood that play the most important role in changing viscoelasticity. It has been shown that low temperature with a high hematocrit leads to a higher viscosity.[165] This elevated viscosity may lead to altered organ perfusion, particularly in the brain. Because of these alterations in blood viscosity, hemodilution is tolerated in the cooling phases of CPB. Although advantageous early, this hemodilution combined with the inflammatory response will lead to transudation of fluid into the extravascular space, which in turn leads to the potential for organ dysfunction as eluded to earlier. Prevention of organ dysfunction and improved oxygenation by the removal of excess fluid and inflammatory mediators are the rationale, therefore, in the use of ultrafiltration. The end result is removal of plasma water and low-molecular-weight solutes across a semipermeable membrane.

Essentially, five forms of ultrafiltration are used in modern perfusion practice, three of which are while the patient is on CPB. Prime ultrafiltration is used when packed RBCs are added to the prime solution and is performed in the prebypass phase; prime ultrafiltration aims to replace crystalloid prime with blood prime, adjust pH, alter electrolyte concentration to safer levels, and remove inflammatory mediators potentially present in the donor blood.[166] Conventional ultrafiltration (CUF) involves the removal of fluid at any time while the patient is being supported by CPB. A common use for this method is removal of the volume of clear fluid equal to the volume of cardioplegia used. CUF can be performed during all phases of CPB. It involves the placement of an ultrafilter within the circuit and connected either to the venous line or the venous reservoir. The removal of an excess of ultrafiltrate will result in low reservoir volumes. In zero balance ultrafiltration, once fluid has been removed it is replaced with crystalloid to avoid inadequate reservoir volume, and thus there is no net removal of volume.

The third method of on-bypass ultrafiltration is dilutional ultrafiltration, which is employed when the concentration of a given electrolyte (e.g., potassium) is deemed elevated.

The method involves removal of ultrafiltrate with its replacement by half with normal saline, thus diluting the concentration of the given electrolyte to safer levels. All on-bypass ultrafiltration have similar end points—that is, attempted removal of excess clear fluid resulting in hemoconcentration, removal of inflammatory mediators, and manipulation of electrolyte concentrations to safe levels.

MUF, first described by Naik and associates[150] in 1991, involves filtration of blood once the patient has been weaned from bypass. This can be achieved either by a venovenous technique in which blood is removed and returned to the atrium once concentrated or by an arteriovenous technique in which blood is removed via the aortic cannula and returned via the venous line.[150,167,168] In more detail, in this technique blood is removed in a retrograde fashion by the aortic cannula and passes through the ultrafilter along with remaining circuit volume from the venous reservoir and oxygenator. Flow through the ultrafilter is maintained by a roller pump at flows of between 10 and 30 mL/kg, with the slower rates resulting in a more gradual change in the intravascular fluid compartment and thus potentially better tolerated. A constant atrial pressure is maintained throughout the procedure by adding crystalloid into the venous reservoir as needed. Suction is applied to the filtrate port to achieve a maximal transmembrane pressure, thus allowing for ultrafiltration rates of between 100 and 150 mL/min. End points for the process of MUF are time (15-20 minutes) and reaching of a target hematocrit (usually 40%) once the circuit volume has been replaced by crystalloid or should the patient's hemodynamics not tolerate the procedure.

Cardiac surgeries in the very young may be complex with potentially protracted CPB and cross-clamp times. Therefore, myocardial performance is more commonly depressed after weaning from CPB. Although ultrafiltration is used during CPB in an attempt to remove excess body water, it appears from studies that it is the use of MUF that significantly improves myocardial performance (Fig. 78.11).[169,170] Using echocardiographic measurements in a study of infants undergoing corrective surgery under nonhypothermic arrested conditions, Davies and associates[171] found improvements in both systolic and diastolic function in the children studied. They found that the preload recruitable stroke work, which is load independent, improved after MUF and was thus a good indicator of improved systolic function. The same study showed that after MUF a decrease in the myocardial wall thickness and cross-sectional area occurred that was not present in the control group of patients who received no ultrafiltration. These reductions result in an increase in end-diastolic length and a fall in end-diastolic pressure, both of which are indicators of improved diastolic function. Although presumably it was the decrease in myocardial edema that was the cause for these improvements, increased hematocrit also was observed. Because these positive effects were not seen past 24 hours, the absolute benefit of MUF is not clear.[171]

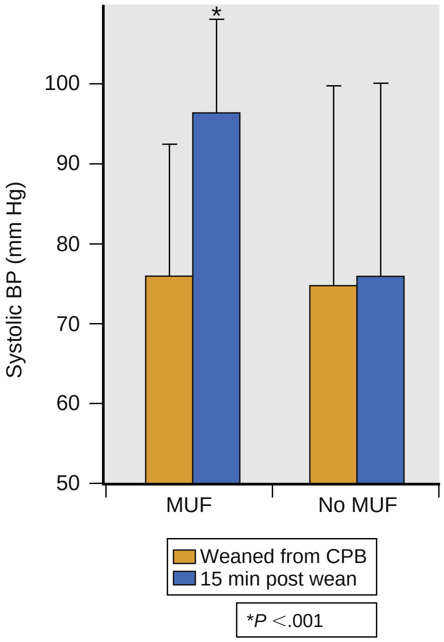

Fig. 78.11 Systolic blood pressure *(BP)* after separating from cardiopulmonary bypass *(CPB)* and 15 minutes after separating with and without modified ultrafiltration *(MUF)*. Note the significant improvement in systolic BP with the use of MUF. (From Ungerleider RM. Effects of cardiopulmonary bypass and use of modified ultrafiltration. *Ann Thorac Surg*. 1998;65:S35; reprinted with permission from the Society of Thoracic Surgeons.)

Pulmonary dysfunction is one of the most common negative effects of CPB[172]; MUF is utilized to improve oxygenation, decrease the effects of inflammatory mediators on the alveolar capillary membrane, and decrease pulmonary vascular reactivity. Studies have demonstrated that in patients in whom ultrafiltration and MUF were used, improvements in pulmonary compliance, decreased airway resistance, pulmonary arterial reactivity, and improved oxygenation were demonstrated.[172-175] It is therefore obvious why these methods have found such wide acceptance in pediatric cardiac surgery, particularly in patients in whom normal compliance with low PVR is vital (i.e., those with single-ventricle physiology). Although these studies commonly find improvement in pulmonary function immediately after weaning from CPB and the completion of MUF, disagreement exists as to whether these effects result in improved function much beyond 6 hours, with some showing little if any benefit at 24 hours. A conclusion, however, from these studies is that combination of on-bypass ultrafiltration coupled with MUF has the best results in the early postbypass period.

In a study performed on a piglet model of DHCA, the use of MUF after CPB improved hematocrit, cerebral O_2 delivery, and cerebral O_2 consumption, thus representing a potential reduction in cerebral injury. Further studies have made similar conclusions, demonstrating that four variables are of importance in improving cerebral oxygenation: PCO_2, mean arterial pressure, hematocrit, and MUF flow rate.[176,177] Increasing all except MUF flow rate improved O_2 delivery. Increasing the flow rate appeared to cause a steal-like phenomenon in which apparent diastolic runoff occurred into the MUF circuit from the aortic cannula. Thus, although the process of MUF is important for recovery of normal cerebral function, care must be used not to negate the benefits by decreasing the time on MUF by increasing the flow rates (Fig. 78.12).

Common to the improvement in cardiac and pulmonary function are the associated decrease in inflammatory mediators seen after ultrafiltration. Studies have shown

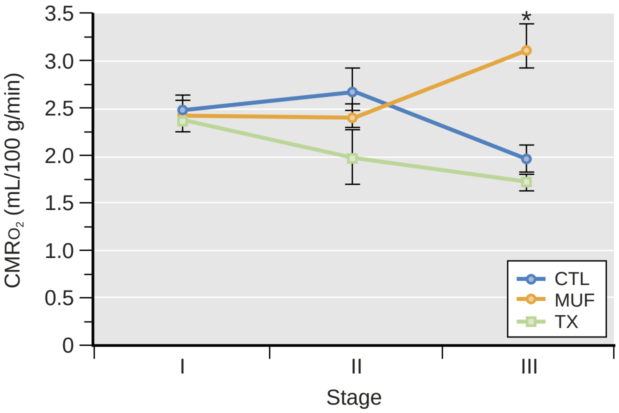

Fig. 78.12 Cerebral metabolic rate for oxygen measurements *(CMRO$_2$)* before and after deep hypothermic circulatory arrest. Note the significant increase in CMRO$_2$ in the MUF animals compared with the control and transfusion groups at stage 3. *CTL,* Control; *MUF,* modified ultrafiltration; *TX,* transfusion. that the ultrafiltrate contains a wide variety of low-molecular-weight inflammatory mediators, including C3a, C5a, interleukin (IL)-6, IL-8, TNF, myocardial depressant factor, and endothelin.[173,178,179] It is the removal of endothelin-1 after MUF that results in the improvement of pulmonary vascular reactivity, which is of great importance, particularly in infants younger than 4 to 6 months of age, when pulmonary vascular reactivity is high, and in patients who are having staged cavopulmonary reconstructions. TNF, a potent inflammatory mediator implicated in the development of capillary leak syndrome seen after CPB, has been shown to be removed best by MUF. Despite these positive effects of MUF, the literature does not give a clear advantage of one form of ultrafiltration over the other, and it may be the combination of these methods that once again shows the best potential results.

Another important post-CPB issue is ongoing blood loss. The use of MUF will result in an elevation of the patient's hematocrit secondary to the removal of the excess body water, as already discussed. This further results in decreased blood use and the observation that there is less postoperative bleeding.[180] Indeed, in older children attempts can thus be made to avoid the use of donor blood altogether.

Disadvantages to these techniques are noted. The addition of an ultrafilter to the CPB circuit adds a level of complexity to the circuitry and thus another potential area in which circuit-related complications may occur. Opponents of MUF note also the following potential problems: the potential for air entrainment into the arterial cannula, additional time in which the patient is anticoagulated, potential for hypovolemia as volume is drawn off from the patient, hypothermia because the filtered volume does not pass through the heater/oxygenator, and the potential for the increase in the plasma concentration of drugs (e.g., fentanyl).[181] Another interesting complication potentially associated with ultrafiltration was the reduction in thyroid hormone. This acute hypothyroidism may lead to depressed function, manifesting as decreased contractility, heart rate, cardiac output, and elevated SVR, all of which will clearly affect the immediate post-CPB period.[182] As with other techniques in medicine the benefit versus risk must be seriously considered, but from the presented evidence the use of ultrafiltration both on and off CPB is extremely beneficial and these methods are thus commonly used in modern pediatric cardiac surgery with good result and little complication.[143,145,183,184]

In the preceding paragraphs the discussion concluded that no clear advantage has been determined of one method of ultrafiltration over the other. Unfortunately, comparing a wide range of patients having different surgeries under different conditions is difficult, and thus it appears that from the articles referenced the best strategy would include both the use of on-CPB ultrafiltration and the use of MUF once the patient has been separated from bypass to achieve the goals of decreasing total-body water; removal of inflammatory mediators; improved hematocrit, and thus O$_2$-carrying capacity; and preservation of vital organ function. With the miniaturization of CPB circuits and resultant reduced hemodilution, some institutions have stopped using MUF because it simplifies and decreases the volume of the CPB circuit. They believe there is an advantage to preventing hemodilution rather than reversing hemodilution with MUF. Significantly miniaturizing circuits is also not without safety concerns as it may limit the ability to increase CPB flow rates. At our institution we continue to use MUF for the many reasons previously described.

SPECIFIC PROBLEMS ENCOUNTERED IN DISCONTINUING CARDIOPULMONARY BYPASS

Left Ventricular Dysfunction

The contractile state of the LV may be reduced after pediatric cardiac surgery, due to surgically induced ischemia during the repair, the preoperative condition of the myocardium, the effects of DHCA on myocardial compliance, and new, altered loading conditions on the LV caused by the repair.[185,186] Left ventricular dysfunction can be treated by optimizing preload, increasing heart rate, increasing coronary perfusion pressure, correcting ionized calcium levels, and adding inotropic support. The neonate's heart rate–dependent cardiac output, reduced myocardial compliance, and diminished response to calcium and catecholamines are factors influencing the need for inotropic support. Inotropic support usually begins with epinephrine 0.03 to 0.05 μg/kg/min or dopamine 3 to 10 μg/kg/min. Several studies suggest that the effect of dopamine in children is age dependent. After cardiac surgery in young children, dopamine increases cardiac output, which correlates more with elevations in heart rate than augmentation of stroke volume, whereas, in young adults, dopamine clearly increases stroke volume. Nonetheless, infants and neonates respond favorably to epinephrine and dopamine infusions with increased systemic arterial blood pressure and cardiac output and improved systemic perfusion.

Calcium supplementation is important in augmenting cardiac contractility. Although calcium supplementation has fallen into some disfavor because of concerns over reperfusion injury, it remains an important therapy after pediatric cardiac surgery. Fluctuations in ionized calcium levels occur commonly in the immediate post-CPB period in children. This is most often due to the relatively large transfusions of citrate-rich and albumin-rich blood products, such as whole blood, fresh frozen plasma, platelets, and cryoprecipitate necessary for hemostasis, all of which bind calcium.[187] Routine calcium supplementation during the early post-CPB period is especially helpful in patients with diminished left ventricular function. In patients with a slow sinus or junctional rate, calcium must be administered cautiously because marked slowing of AV conduction may occur.

Epinephrine 0.02 to 0.2 μg/kg/min is useful in patients with significant left ventricular dysfunction who remain hypotensive with high left atrial filling pressures or echo-Doppler imaging evidence of reduced contractility or regional ischemia.[188]

Milrinone, a potent phosphodiesterase-3 inhibitor, is also an effective inotrope-vasodilator in infants and children. Studies in neonates after open-heart surgery reveal significant reductions in SVR and PVR and increases in cardiac index, primarily as a result of larger stroke volume.[189] Infants and children demonstrate a larger volume of distribution and clearance of milrinone than that in adults; thus, the initial loading dose necessary to achieve therapeutic levels may be as large as 100 μg/kg.[190] In neonates, the initial dose of milrinone on CPB is 25 to 100 μg/kg, followed by a continuous infusion to be started within 90 minutes of the initial dose at a rate of 0.2 μg/kg/min to maintain a therapeutic level. In older infants and children, the rate of continuous infusion is larger, usually 0.5 to 1 μg/kg/min.

Dobutamine is an effective, albeit weaker, inotropic agent in children. Although it is reported to have a lesser chronotropic effect than dopamine in neonates, significant tachyarrhythmias may occur. This may be related to structural similarities between dobutamine and isoproterenol.[188] In children after cardiac surgery, dobutamine increases cardiac output primarily through increased heart rate. This is consistent with reduction in α-receptors and a higher level of circulating catecholamines in newborns.

Right Ventricular Dysfunction

Primary right ventricular dysfunction is a common finding after CPB in neonates, infants, and children. For example, after repair of TOF, preexisting right ventricular hypertrophy, a right ventriculotomy, and the placement of a transannular patch across the right ventricular outflow tract, resulting in acute pulmonary regurgitation and right ventricular volume overload, are common causes of postoperative right ventricular dysfunction.[17] The treatment of right ventricular dysfunction consists of measures directed at lowering PVR and preserving coronary perfusion without distending the RV. In cases of ventricular dysfunction, low-dose epinephrine (0.01-0.03 μg/kg/min) may provide inotropy without vasoconstriction.[186] Mechanical ventilation should be adjusted to assist right ventricular function and minimize PVR.

In contrast to the LV, the low intracavitary pressure of the normal RV receives two thirds of its coronary filling during ventricular systole. In patients with right ventricular dysfunction, maintaining a normal or slightly elevated systolic arterial pressure maximizes coronary perfusion to the RV and augments contractility. A vasopressin infusion can prove advantageous in such circumstances. If the need for inotropic support persists after the early post-CPB period, a critical evaluation for other structural and functional abnormalities should be aggressively pursued. Preload should be maintained at a normal to slightly elevated level. Because right ventricular contractility is reduced, it is important to maximize preload to the highest portion of the Starling curve. Overdistention of the RV, however, is not well tolerated, owing to diminished ventricular compliance and diastolic dysfunction. Excessive volume loading may result in significant diastolic dysfunction, tricuspid regurgitation, and worsening forward flow. Generally, CVP much above 12 to 14 mm Hg is poorly tolerated in neonates and infants with right ventricular dysfunction.[191] If right ventricular dysfunction is severe, the sternum should be left open.[192] This eliminates the impedance imposed by the chest wall and mechanical ventilation, allowing the RV to maximize its end-diastolic volume. An additional strategy in neonates, infants, and children with significant post-CPB right ventricular dysfunction is to allow right-to-left shunting at the atrial level. Typical patients who would benefit from this strategy include neonates undergoing repairs for TOF and truncus arteriosus. Allowing an atrial communication to remain open, with blood shunting in a right-to-left direction, preserves cardiac output and O_2 delivery to the systemic circulation. Although these patients have somewhat diminished systemic O_2 saturation, their effective cardiac output and tissue O_2 delivery are enhanced, systemic perfusion pressure improves and coronary perfusion of the RV is maintained. As right ventricular function improves, right atrial pressure falls, right-to-left shunting decreases, and systemic arterial saturation rises.

If right ventricular dysfunction persists to the extent that systemic cardiac output is compromised, consideration should be given to extracorporeal life support (extracorporeal membrane oxygenation [ECMO]). When ECMO is used for circulatory support, venoarterial cannulation is preferred. Venous and arterial access may be achieved through a large central artery and vein, usually the carotid artery and internal jugular vein, or by direct chest cannulation. Recovery from severe ventricular dysfunction is predicated on the concept that the myocardium has sustained a transient injury (i.e., “stunned myocardium”) and is capable of recovery with time.[193,194] ECMO is used to decrease ventricular wall tension, increase coronary perfusion pressure, and maintain systemic perfusion with oxygenated blood. ECMO also may be used for left ventricular failure, although success with this condition is less common than that seen with right ventricular dysfunction or pulmonary artery hypertension. Patients placed on ECMO because they fail to separate from CPB demonstrate significantly greater mortality than do those for whom ECMO was instituted later in the postoperative course.[195] The children who consistently have the lowest survival rate are those who require ECMO after a Fontan operation.[196] The role of ECMO in patients with myocardial injury or pulmonary hypertension is to provide adequate systemic O_2 transport and systemic perfusion while allowing the ventricles to rest and recover. ECMO may even provide an effective means of resuscitation for postoperative cardiac patients, particularly if instituted promptly.[197] In larger infants and children with predominantly right ventricular dysfunction and satisfactory pulmonary function, a selective right ventricular assist device (VAD) may be preferable to ECMO.[198]

Pulmonary Artery Hypertension

Primary pulmonary hypertension is a devastating disease. The progressive and sustained elevation in PVR eventually leads to right-sided HF and death.[199,200] Pulmonary arterial hypertension (PAH) is defined by the presence of mean pulmonary arterial pressure greater than 25 mm Hg at rest or 30 mm Hg during exercise.[201] In two studies, the presence of PAH was shown to be a significant predictor of major perioperative cardiovascular complications, including pulmonary hypertensive crises, cardiac arrest, and death in patients undergoing cardiac catheterization or noncardiac surgery under anesthesia.[202,203] Suprasystemic pulmonary artery pressure was predictive of major complications. Complications, however, were not associated with age, cause, type of anesthetic, or airway management. Preanesthesia evaluation should gauge disease severity. A history significant for chest pain, syncope, and dizziness, with signs of dyspnea at rest, low cardiac output state, metabolic acidosis, hypoxemia, and signs of right-sided HF warrants caution. Acute increases in PVR resulting in pulmonary hypertensive crises cause an increase in right ventricular afterload, right ventricular dysfunction, and hemodynamic decompensation. Suprasystemic pulmonary artery pressure results in inadequate PBF, inadequate left ventricular preload, low cardiac output, and biventricular failure. The associated hypotension results in coronary ischemia, which worsens this cycle. Perioperative factors thought to precipitate a pulmonary hypertensive crisis include hypoxia, hypercarbia, acidosis, hypothermia, pain, and airway manipulations in patients with pulmonary hypertension. Such patients present for hemodynamic catheterization, drug study, and noncardiac and cardiac surgical procedures. Although each anesthetic has to be tailored to the patient's pathophysiologic condition and surgical procedure, certain common principles remain. Pulmonary vasodilator therapy and inotropes must be continued in the perioperative period. Investigations include a comprehensive echocardiogram with occasional chest computed tomography angiography to exclude pulmonary thromboembolic disease. After premedication, the patient should be monitored with pulse oximetry to ensure the patient does not hypoventilate or become hypoxic. An intravenous induction with carefully titrated doses of ketamine may be the safest; if no intravenous is present, an inhalational induction with sevoflurane can be performed safely with 100% O_2, keeping the end-tidal sevoflurane concentration as low as possible and quickly obtaining intravenous access. Procedures with potential for blood loss, hemodynamic instability, and changes in ventilatory status mandate invasive arterial monitoring. Care should be taken to avoid systemic hypotension while achieving general anesthesia. Ventilation and oxygenation are controlled, and acidosis is treated aggressively. Hypotension in the presence of euvolemia may need to be treated with inotropes and, if necessary, α_1-agonists.[204,205]

Therapy for elevated pulmonary artery pressures is directed at lowering PVR and unloading the RV. Reduction of PVR is accomplished by altering ventilation pattern, inspired O_2 concentration, and blood pH. Specifically, manipulating the pulmonary vascular bed in newborns and infants is a matter of regulating partial pressure of CO_2 in arterial blood ($PaCO_2$), pH, PaO_2, partial pressure of alveolar oxygen, and ventilatory mechanics.[206,207] $PaCO_2$ is a potent mediator of PVR, especially in the newborn and young infant. Reducing $PaCO_2$ to 20 mm Hg and increasing pH to 7.6 produces a consistent and reproducible reduction in PVR in infants with pulmonary artery hypertension. Manipulating serum bicarbonate levels to achieve a pH of 7.5 to 7.6 while maintaining a $PaCO_2$ of 40 mm Hg has equal salutary effects on PVR.[208] An increase in the FiO2 and the PaO_2 decreases PVR as well. In the circumstance of intracardiac shunts, changes in FiO_2 have little effect on PaO_2. Thus, by inference, a reduction in PVR induced by increasing the inspired O_2 concentration is probably a direct pulmonary vasodilatory effect of PaO_2 rather than FiO_2.

Ventilatory mechanics also play a major role in reducing PVR. Neonates and infants have a closing volume above functional residual capacity. Thus, at the end of a normal breath, some airway closure occurs. This process results in areas of lung that are perfused and yet underventilated. As these lung segments become increasingly hypoxemic, secondary hypoxic vasoconstriction occurs. The net effect is an increase in PVR. Therefore, careful inflation of the lungs to maintain functional residual capacity will selectively reduce PVR. In practice, this is accomplished with relatively large tidal volumes and low respiratory rates, which produce an exaggerated chest excursion. Respiratory rates of 15 to 25 breaths/min are used for neonates and infants.

Because PBF occurs predominantly during the expiratory phase of the respiratory cycle, the ventilatory pattern should be adjusted to allow an adequate distribution of gas throughout the lung during inspiration and a more prolonged expiratory phase to promote blood flow through the lungs. End-expiratory pressure must be applied cautiously during the post-CPB period. Low positive end-expiratory pressure (PEEP) (3-5 mm Hg) prevents narrowing of the capillary and precapillary blood vessels, thereby reducing PVR. Higher PEEP or excessive mean airway pressure results in alveolar overdistention and compression of the capillary network in the alveolar wall and interstitium. This condition elevates PVR and reduces PBF.[153]

The final and perhaps the least well-recognized use of the mechanical ventilator is to assist in unloading the RV. During positive pressure inspiration, intrathoracic pressure increases and creates an increased pressure gradient from the lung to the LA, promoting cardiac output. This ventilatory assist is commonly seen in patients with PAH or right ventricular dysfunction. An augmentation of the arterial pressure trace during inspiration is seen. The use of the ventilator to augment systemic blood flow is very similar to the thoracic pump concept used to explain blood flow during CPR.[209] The inspiratory assist must be balanced by the potential negative effects of increased mean airway pressure on PVR and right ventricular afterload. To maximize these cardiopulmonary interactions, high tidal volume with low respiratory rates should be employed.

Attempts to manipulate PVR through pharmacologic interventions are also possible. Drugs that have shown promise in decreasing PVR both clinically and experimentally have been the phosphodiesterase inhibitors such as amrinone and milrinone. Both reduce PVR and SVR and increase RV contractility.[210] Isoproterenol has mild pulmonary artery–vasodilating properties in the normal pulmonary circulation.[211] It reduces PVR in adults after cardiac transplantation, but very few data support PVR reduction in infants and young children after cardiac surgery. In immature animals, the myocardium is less responsive to isoproterenol and causes tachycardia and increased myocardial O_2 consumption. These latter effects may reduce coronary perfusion and result in relative myocardial ischemia. Both prostaglandin E1 and prostacyclin have a pulmonary vasodilating effect; however, both drugs produce systemic hypotension, which severely limits their use.[212,213]

There are now ultra–short-acting intravenous vasodilators and inhaled vasodilating agents such as NO. Ultra–short-acting intravenous vasodilators are nonspecific potent vasodilators, with a half-life of seconds. Infusion of these drugs into the right side of the circulation produces a potent short-lived relaxation of the pulmonary artery smooth muscle.[214] Once the drug reaches the systemic circulation it is no longer functional. Adenosine and ATP-like compounds have these properties and may have clinical applicability in pulmonary artery hypertension in the future.[215]

Beginning in the past decade, several potent therapies for pulmonary hypertension have evolved.[206,207] A continuous intravenous infusion of prostacyclin improves pulmonary vascular hemodynamics, exercise tolerance, and survival in pulmonary hypertension.[216] Sildenafil is a selective phosphodiesterase type 5 inhibitor. Phosphodiesterase type 5 breaks down cyclic guanosine monophosphate. Sildenafil produces acute and relatively selective pulmonary vasodilatation and acts synergistically with NO.[217-219] Bosentan is a dual endothelin receptor blocker. Preliminary reports indicate that bosentan improves symptoms, exercise tolerance, and hemodynamics in patients with pulmonary hypertension. The drug is well tolerated and free of side effects apart from a dose-dependent increase in liver enzymes.[220] Lung transplantation is the only available surgical therapy for primary pulmonary hypertension; however, the 5-year survival remains less than 50%, and bronchiolitis obliterans remains the single most common cause of death.[221,222] Before listing for transplantation, all patients undergo a hemodynamic cardiac catheterization and drug study in which reversibility of pulmonary hypertension with increased inspired O_2 concentrations and NO is determined.[223] Prostacyclin analogues including inhaled iloprost or intravenous epoprostenol, although used in adult centers, have not become routine in pediatric practice.

CPB with associated endothelial injury predisposes to the development of postoperative pulmonary hypertension in patients with CHD. Anatomic factors that impose either obstruction to PBF or residual left-to-right shunting need to be surgically addressed. Elevated LAP resulting from mitral valve disease or left ventricular dysfunction, pulmonary venous obstruction, branch pulmonary artery stenosis, or surgically induced loss of the pulmonary vascular cross-sectional area all raise right ventricular pressure and impose a burden on the right side of the heart.

NO, an endothelium-derived vasodilator that is administered as an inhaled gas, represents the most promising development in the therapy for elevated PVR in patients with CHD. Although nonselective, it is rapidly inactivated by hemoglobin and, when inhaled, produces no systemic vasodilation.[224] NO reduces pulmonary artery pressure in adult patients with mitral valve stenosis and in selected pediatric cardiac patients with PAH.[225-227] The congenital cardiac patient population in whom NO appears to be effective is patients with acute PVR elevation after open-heart surgery, as well as preoperative pulmonary hypertension accompanying specific anatomic conditions (e.g., total anomalous pulmonary venous return, congenital mitral stenosis).[225,227] Because it acts directly on vascular smooth muscle, NO remains effective despite the post-CPB endothelial injury frequently encountered in children.[228] Some centers routinely employ low-dose NO (1-5 ppm) after a Fontan operation when the CVP-LAP gradient exceeds 10 mm Hg.[229] At our institution, a dose of 20 ppm is the standard dose in both the ICU and the cardiac operating room. Finally, NO can provide diagnostic information that helps distinguish reactive pulmonary vasoconstriction from fixed anatomic obstructive disease either in the postoperative surgical patient or in the patient undergoing pre-transplant evaluation.[230,231] In the latter, the distinction between pulmonary vasoconstriction and advanced pulmonary vascular occlusive disease will influence the prediction as to whether a child with pulmonary hypertension in association with either CHD or cardiomyopathy will survive a heart transplant or requires replacement of both heart and lungs.

Management strategies for postoperative pulmonary hypertension and treatment of pulmonary hypertensive crises include sedation, moderate hyperventilation (maintaining CO_2 partial pressure [PCO_2] between 30 and 35 mm Hg), moderate alkalosis (pH > 7.5), increased inspired O_2, optimization of PEEP (to maximize functional residual capacity), pulmonary vasodilators (e.g., NO), and the creation or maintenance of an intracardiac right-to-left shunt in an attempt to maintain cardiac output.[232,233] NO is also useful in the manipulation of PVR after Fontan-type procedures.[234] Care should be exercised in weaning NO in patients, because abrupt withdrawal can precipitate rebound pulmonary hypertension and pulmonary hypertensive crises.[234,235]

Anticoagulation, Hemostasis, and Blood Conservation

Pediatric anesthesiologists must manage coagulation, hemostasis, and blood conservation in the perioperative period of cardiac surgery. Coagulopathy after CPB remains a significant problem in pediatric cardiac surgery.[223] Continuing blood loss after CPB requiring blood component replacement is associated with hemodynamic compromise as well as morbidity. In pediatric patients, restoration of hemostasis has proved difficult; diagnosis of the problem and treatment are marginally effective.

Neonates, infants, and children undergoing cardiac surgery with CPB have a higher rate of postoperative bleeding than that seen in older patients.[236] First, the ratio of patient body surface area to the nonendothelialized extracorporeal circuit volume is disproportionate; the relatively large inflammatory-type response provoked in response to CPB is inversely related to patient age—the younger the patient, the more pronounced is the response.[9] Because complement and platelet activation are linked to the activation of other protein systems in the blood (i.e., fibrinolytic proteins), it is probable that this hemostatic activation, which results in impaired hemostasis and increased bleeding tendency, plays a major role during pediatric cardiac surgery. Second, the type of operation performed in neonates and infants usually involves more extensive reconstruction and suture lines, creating more opportunities for surgical bleeding than in adult cardiac patients. Operations are also frequently performed using DHCA, which may further impair hemostasis.[237] Third, the immature coagulation system in neonates is also likely to contribute to impaired hemostasis.[238] Although procoagulant and factor levels may be reduced in young patients with CHD resulting from immature or impaired hepatosynthesis,[239] functional bleeding tendencies are usually not present before surgery. Furthermore, compounding the problem of immature coagulation proteins is the massive hemodilution that occurs when initiating CPB in infants and small children. Despite advances in circuit miniaturization, initiation of CPB induces a dilutional thrombocytopenia and reduces levels of factors II, V, VII, VIII, IX, X, ATIII, and fibrinogen.[240] Patients with cyanotic heart disease demonstrate an increased bleeding tendency before and after CPB because of a range of factors including thrombocytopenia, low numbers of von Willebrand factor multimers, clotting factor deficiencies, and poor fibrinogen function.[241]

CPB is a significant stimulant of the coagulant and inflammatory systems, requiring anticoagulation with heparin before its initiation. Heparin is traditionally administered based on patient weight, at an empiric dose of 400 units/kg. Adequacy of heparinization is monitored by the activated clotting time (ACT), a measure of inhibition of the contact activation pathway, with a goal ACT of greater than 480 seconds prior to initiation of CPB. An accurate ACT requires normothermia, normal platelet count and function, and normal levels of other coagulation proteins including antithrombin III. As these derangements are common in children having cardiac surgery, the ACT may not be the ideal monitor of anticoagulation in this population. In neonates, infants, and young children, the ACT does not correlate with plasma heparin concentration,[242] and children exhibit evidence of ongoing thrombin generation and coagulation activity despite very high ACT values.[243]

An alternative to weight-based heparin dosing is use of a blood heparin concentration-based system, which utilizes protamine titration to indicate whole blood heparin concentration at the bedside. Such a setup allows for individual variability in heparin efficacy and metabolism. Although blood heparin concentration devices have shown disappointing results in adults, results in children suggest greater suppression of thrombin generation and hemostatic activity,[244] reduced number of blood transfusions, and improvement in clinical outcomes of ventilator hours and ICU stay.[245] Blood heparin concentration systems also account for bypass circuit characteristics when deciding heparin dose in the bypass prime. In the absence of such a system, empiric dosing is recommended at 1 to 3 units/mL of priming solution.

An important caveat to anticoagulation management in infants is the role of antithrombin III, the body's most abundant natural anticoagulant and target for heparin efficacy. Neonates have low levels of antithrombin III activity,[246,247] and those with CHD have a functional antithrombin III level of approximately 50%.[248] Heparin exerts its anticoagulant effect by accelerating the reaction between thrombin and antithrombin. Low antithrombin activity is one reason for low heparin sensitivity in the pediatric cardiac population; however, large clinical trials examining antithrombin III replacement have not been conducted. In addition, other heparin cofactors, including α_2-macroglobulin, may play an important, though poorly understood, role in anticoagulation in young children.[249]

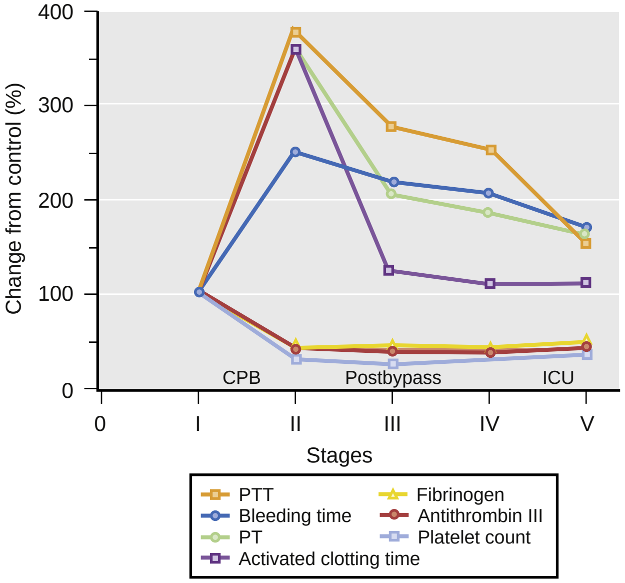

Fig. 78.13 Plot of blood coagulation profile changes before, during, and after cardiopulmonary bypass *(CPB)* in 25 children. Clotting times and coagulant factors are shown as percent change from control. Stage I, baseline, before CPB; stage II, post-CPB, before protamine reversal of heparin; stage III, after protamine; stage IV, just before leaving the operating room; stage V, after 3 hours in the intensive care unit *(ICU)*. *PT,* Prothrombin time; *PTT,* partial thromboplastin time.

Heparin is neutralized with protamine according to the quantity of heparin administered or based on body weight, usually 2 to 4 mg/kg, accounting for heparin administered to the patient only (excluding heparin added to the pump prime). Blood heparin concentration devices may be used to dose protamine according to the amount of circulating heparin in the patient, accounting for metabolism or recent dosing. Delayed hepatic clearance of heparin resulting from organ immaturity and the predominant use of hypothermic circulatory arrest in the young decrease metabolism and excretion of heparin. Younger children require relatively more protamine compared to older children and adults, as reflected by higher circulating heparin levels after CPB.[250] Prolonged ACT after adequate protamine dosing may indicate platelet dysfunction, hypofibrinogenemia, or other coagulation abnormalities. This should be assessed before administering additional protamine, which in excess may contribute to postoperative bleeding.[251]

Bleeding after CPB is not an unusual occurrence. The surgeon should first attempt to identify any obvious source of surgical bleeding at the sites of repair. In general, standard coagulation tests show a prolongation of the partial thromboplastin time, prothrombin time, hypofibrinogenemia, dilution of other procoagulants, and prolonged bleeding time in many pediatric patients, with and without bleeding (Fig. 78.13). The most common reason for persistent bleeding is platelet dysfunction,[252-254] and empiric platelet administration can be warranted. Routine administration of blood products to correct laboratory coagulation abnormalities in the absence of bleeding is never clinically indicated. Under most circumstances, meticulous surgical technique, appropriate administration of protamine, adequate patient temperature, and platelet infusion will correct excessive bleeding.

Risk factors for bleeding after bypass include lower body weight,[255,256] lower temperatures on bypass,[257] resternotomy,[257] preoperative congestive HF,[257] and presence of cyanotic CHD.[256] In these populations, a more aggressive approach is warranted. Although use of transfusion algorithms demonstrate reduced transfusion and even decreased mortality in adults having cardiac surgery,[258,259] no large or multicenter trials have been conducted examining transfusion algorithms in children. Complicating the development of algorithms in children is the heterogeneity in congenital defects, the surgical operation performed, and the complexity across congenital heart centers.[260]

However, several single-center studies show that use of viscoelastic testing (particularly rotational thromboelastography) to guide transfusion after bypass surgery may reduce transfusion requirement[256,261,262] and ICU days.[262] These studies provide reasonable thresholds for initiating transfusion after bypass as guided by rotational thromboelastometry (ROTEM) parameters, but no large prospective studies have been conducted to validate the targets. Importantly, use of either thromboelastography or ROTEM in children having cardiac surgery must be interpreted against age-appropriate reference values.[263,264]

Pharmacologic interventions are increasingly used to reduce bleeding after CPB. Antifibrinolytics exert their effects by reversibly binding to lysine analogue sites on plasminogen, a molecule primarily responsible for the breakdown of fibrin. By inhibiting plasminogen, and therefore plasmin, the procoagulant effects of fibrin remain. Lysine analogues epsilon amino-caproic acid and tranexamic acid are efficacious in reducing bleeding and transfusion requirement in pediatric cardiac surgery.[265] A large-scale observational study of 22,258 patients found that the serine protease inhibitor aprotinin had effects similar to those of both aminocaproic acid and tranexamic acid in terms of reducing bleeding requiring surgical intervention and mortality.[266] Unfortunately, aprotinin was removed from the United States market because of concerns of life-threatening anaphylactic reactions.[237,267-271] Dosing schemes for antifibrinolytic therapy are variable, though neonates require reduced loading and infusion doses compared to older children and adults because of decreased clearance.[272] After bypass surgery, desmopressin acetate has been administered to improve platelet function with variable success in reducing postoperative blood loss.[273,274]

Factor concentrates are increasingly used off-label in pediatric cardiac populations to provide needed coagulation factors in small children who may not tolerate the volume of fresh frozen plasma or cryoprecipitate required to satisfactorily raise factor levels.[275] Observational evidence suggests that recombinant activated factor VII is efficacious as a rescue agent for protracted after-bypass bleeding, after the transfusion of platelets, fibrinogen, and coagulation factors to provide adequate scaffolding for its action.[275] Fibrinogen concentrate has also been used to replace fibrinogen in pediatric cardiac patients and may be used in place of cryoprecipitate.[276] Prothrombin complex concentrates (PCCs) are purified plasma-derived products containing vitamin-K–dependent clotting factors (II, VII, IX, X) in either 3- (3F) or 4- (4F) factor preparations. PCCs are included in many transfusion algorithms in adult cardiac surgical populations but the safety and efficacy in pediatrics remains understudied.[277] Both 3- and 4-factor PCC improve thrombin generation in ex vivo studies of neonatal plasma,[278,279] but most evidence for clinical use is limited to case reports or small case series. At our institution, we administer 3-factor PCC as part of a transfusion algorithm in severe hemorrhage, after replacement of platelets, fibrinogen, and other coagulation factors.

Blood transfusion during the perioperative period must be thoughtful and intentional. Injudicious use of blood products to correct individual coagulation abnormalities separately further exacerbates dilution of existing procoagulants, and carries the risk of multiple donor exposures. Transfusion should be undertaken as specifically indicated by an impairment in tissue oxygenation or documented coagulopathies with clinically significant bleeding. Interestingly, while transfusion algorithms may reduce transfusion, in pediatric populations they may be more likely to alter the pattern of transfusion,[262] for example decreasing RBC transfusion while increasing platelet and cryoprecipitate use. Algorithms may improve hemodynamic stability[262]; research is needed to confirm improved outcomes.

Determining the optimal hematocrit is necessary to guide transfusion and is best decided in conjunction with the surgeon based on an individual patient's lesion, complexities, and planned procedure. RBCs should be administered to maintain a postdilutional hematocrit of at least 20% on CPB[280]; children with cyanotic CHD require a higher hematocrit. A recent study demonstrated an association between the indication for blood transfusion and postoperative morbidity in a cohort of children having cardiac surgery. Study results indicated that patients who required transfusion to maintain a target postdilutional hematocrit on pump had no increase in morbidity, while those requiring a therapeutic transfusion experienced severe morbidity and mortality.[281]

An increasingly recognized problem in pediatric cardiac surgical populations is thrombosis. Approximately 11% of children having cardiac surgical procedures experience a thrombotic complication[282]; risk factors include younger age,[282,283] cyanotic disease,[282,283] use of DHCA,[282] longer duration of in situ central lines,[282] and administration of blood products in the absence of intraoperative coagulation testing.[284] Alterations in levels of pro- and anti-coagulants in the immature pediatric patient combined with the inflammatory effects of bypass create a hypercoagulable state in many patients postoperatively.[285] Decreased antithrombin III levels after cardiac surgery are associated with thrombotic events in adults[286] but this has not been evaluated in children. Further, the ability of the infant's immature antifibrinolytic system to lyse clots composed of adult fibrinogen may be impaired.[287]

The techniques of thoughtful transfusion and blood conservation must be continued as the patient is transferred to the ICU. Isolated coagulation abnormalities are often present in the postoperative patient with uncomplicated cardiac issues (see Fig. 78.13), but are not associated with excessive bleeding and self-correct during the first postoperative day. Routine correction of these abnormalities with infusion of blood products is not warranted. Administration of blood products should not occur in the absence of clinical evidence of bleeding and the identification of a specific defect requiring targeted component therapy. Routine use of blood products for volume replacement is also to be avoided; lactated Ringer or saline solution can be satisfactorily administered at a reduced cost without the hazards associated with transfusion.

Postoperative Management

Immediate postoperative care of the pediatric patient who has undergone cardiothoracic surgery is an important period in the overall sequence of anesthetic and surgical management. Although the primary influence on outcome is determined by the conduct of the operation, postoperative care is an important factor. As a member of the operative team, it is necessary that the anesthesiologist understand and become involved during the immediate postoperative period. Detailed principles of postoperative management of pediatric cardiac surgical patients are beyond the scope of this chapter. However, a few general guiding principles and approaches are given to provide fundamental knowledge for the anesthesiologist.

The postoperative period can be characterized by a series of physiologic and pharmacologic changes as the body convalesces from the abnormal biologic conditions of CPB and cardiac surgery. During this period, the effects of the cardiac operation, any underlying disorders, the effects of hypothermic CPB, and special techniques such as DHCA may create special problems. In the immediate postoperative setting, abnormal convalescence and specialized problems must be recognized and managed appropriately. Fortunately, most patients are able to balance the cost imposed by the physiologic trespass created by the surgical repair and the effects of CPB against the benefit of reduced pathophysiologic loading conditions, resulting in low morbidity and mortality.

Therefore, the guiding principle in the management of the postoperative patient is an understanding of both normal and abnormal convalescence after anesthesia and cardiac surgery. The immediate postoperative period, even that of normal convalescence, is one of continuous physiologic change because of the pharmacologic effects of residual anesthetic agents and the ongoing physiologic changes secondary to abrupt alteration in hemodynamic loading conditions, surgical trauma, and extracorporeal circulation. Anesthesia and surgery affect not only the patient's conscious state but also cardiovascular, respiratory, renal, and hepatic function; fluid and electrolyte balance; and immunologic defense mechanisms. Despite these changes, postoperative care should be predictable and standardized for most patients undergoing cardiac procedures.

In general, the four temporal phases of postoperative management in the cardiac patient are (1) transport to the ICU, (2) stabilization in the ICU, (3) weaning from inotropic and ventilatory support, and (4) mobilization of fluids. Patients proceed through these phases at variable rates based on such factors as the underlying disease process, preoperative medical condition, sequelae of the surgical procedure, duration of CPB, and presence or absence of intraoperative complications. One of the most important functions of the ICU team is to identify postoperative complications in the patient who convalesces abnormally and to provide interventional therapy. Because physiologic change after cardiac surgery is dramatic but self-limiting during normal convalescence, recognition of abnormal processes can be difficult. Under such circumstances a uniform, multidisciplinary approach with experienced clinicians and nurses facilitates the identification of any abnormalities in convalescence. These abnormalities often are indications for closer observation, more invasive monitoring, pharmacologic intervention, and increased cardiopulmonary technical support. Complications include hypovolemia, residual structural heart defect, right and left ventricular failure, hyperdynamic circulation, pulmonary artery hypertension, cardiac tamponade, arrhythmias, cardiac arrest, pulmonary insufficiency, oliguria, seizures, hypercoagulable state, thrombosis, and brain dysfunction. It is critical to detect these departures from the normal convalescent course and to treat them aggressively.

One important area in which the anesthesiologist can aid the recovery of the cardiac patient is pain control. Pain and sedation are among the most common problems requiring ICU intervention. Many factors influence the onset, incidence, and severity of postoperative pain. The attenuation of the stress response in the immediate postoperative period using infusions of potent opioids in the critically ill infant reduces morbidity.[95] Attenuation of postoperative pain can be attempted with a preoperative medication and an intraoperative anesthetic management technique that includes the use of potent opioids. Patients who receive no opioids preoperatively or during the operative procedure will require analgesics in the immediate postoperative period once the inhalation anesthetic is eliminated. Most cases of postoperative pain can be managed by the administration of small intravenous doses of opioids, usually morphine or hydromorphone. This is important in a patient being weaned from the ventilator during the early postoperative period. Patients who are intubated and ventilated overnight should receive adequate sedation and pain control until ventilatory weaning is begun. This is usually accomplished by a continuous infusion of a benzodiazepine and an opioid. Continuous infusion of sedatives and analgesics results in a more consistent and reliable control of postoperative pain. When separated from mechanical ventilation, the patient is concurrently weaned from the sedatives and analgesics. In patients with reactive pulmonary artery hypertension, opioids have been shown to prevent hypertensive crisis.[92]

Regional anesthesia may be used for postoperative pain control in infants and children after thoracotomy. This method avoids opioid-induced respiratory depression from intravenous doses of these drugs. The administration of opioids in the epidural space is a very effective approach to pain management. This technique is used in children for postoperative pain control via the caudal route as a "single shot" or by a small caudal catheter. Morphine or hydromorphone provides effective analgesia with a duration of 6 to 12 hours, with no significant respiratory depression. Caudal morphine 0.05 to 0.075 mg/kg delivered in a total volume of 1.25 mL/kg of sterile saline has been used with good success in our practice. The use of regional anesthesia for postoperative pain appears to be best suited for the child extubated in the early postoperative period. Relative contraindications of this technique include hemodynamic instability and patients with abnormal clotting profiles and/or continued active bleeding. Using regional analgesia can result in better arterial oxygenation, a more rapid ventilator weaning, and decreased postoperative respiratory complications. However, urinary retention occurs frequently in patients without a bladder catheter.

Children requiring large thoracotomies or a bilateral thoracosternotomy (i.e., "clamshell") incision merit consideration for thoracic epidural analgesia. This technique significantly reduces the respiratory depression and pulmonary mechanics abnormalities that accompany the quantity of systemic opioids that would be necessary to provide adequate analgesia for these excruciatingly painful incisions. If the procedure requires systemic heparinization, we will typically defer placement of these catheters until the heparin effect is neutralized. For the patient undergoing coarctation repair via a left thoracotomy there is some concern for paraplegia following the operation. However, as the incidence of paraplegia in children is exceedingly low, we usually choose to place the caudal or epidural catheter before surgical incision to maximize the benefit intraoperatively; however some centers choose to place it at the end of surgery after it is clear there is no neurologic impairment. For patients undergoing heart, lung, or dual transplantations, a thoracic epidural catheter is placed at a time in the postoperative period when the patient can be weaned from intravenous medications that would adversely affect the patient's ability to breathe in close proximity to the planned extubation. It is helpful for these patients to have a functioning thoracic epidural catheter for several days.

POSTOPERATIVE NEUROPSYCHOLOGIC MORBIDITY

Neurologic morbidity has been identified to be increasingly problematic in neonates and infants with CHD as surgical mortality rates have improved. Although early postoperative CNS sequelae such as stroke and seizures occur in a small percentage of neonates with CHD, the importance of more subtle neurologic abnormalities at long-term follow-up is being increasingly recognized.[222,231,288]

These findings may include fine and gross motor impairments, speech and language delays, disturbances in visual-motor and visual-spatial abilities, attention-deficit disorders, learning disorders, and impaired executive functioning. The presence of congenital brain disease in patients with CHD represents a challenge in improving long-term neurologic outcomes. Many neonates with CHD have congenital structural brain abnormalities, chromosomal abnormalities, or both, as well as physiologic abnormalities that may impair brain development. Brain abnormalities on head ultrasonography have been noted in one fifth of full-term infants undergoing heart surgery, with half of them being present preoperatively.[288]

Postoperatively, secondary neurologic injury may be related to post-CPB alterations in cerebral autoregulation and additional hypoxic-ischemic insult, seizures, or other issues associated with prolonged ICU stay. In addition to prenatal and modifiable perioperative factors, genetic and environmental factors are known to be important. Unfortunately, modifiable perioperative factors may explain less of the variability in long-term outcomes than do patient-specific factors.

New, postoperative neurologic injury may be detected clinically in over 10% of infants,[288a] increasing to over 50% using more sensitive brain imaging techniques such as MRI.[289,290] Given that new neurologic injury can occur at various time points during the neonate's hospitalization, perioperative attention to reducing known risk factors is critical. Mechanisms of CNS injury in infants undergoing cardiac surgery include hypoxia-ischemia, emboli, reactive O_2 species, and inflammatory microvasculopathy. Preoperatively, the primary focus is on preventing hypoxic-ischemic injury and thromboembolic insults. Modifiable intraoperative factors associated with CNS injury include, but are not limited to, pH management, hematocrit during CPB, regional cerebral perfusion, and the use of DHCA. The adverse effects of CPB may be greater in infants than larger children or adults given the immaturity of their organ function and tissues, and the size of the CPB circuit relative to their body size.[291] However, a significant amount of research has been conducted in the area of intraoperative prevention of neurologic injury. With ongoing changes in technology and new therapies, the conduct of CPB and other support techniques have been actively under investigation.

The developmental consequences of exposure to general anesthetics are not well understood and are difficult to elaborate on in the absence of prospective randomized controlled trials, because of multiple factors that affect neurologic outcome in this population. Current literature suggests that multiple exposures, cumulative doses of exposure, and exposure in infancy might increase the risk for neurodevelopmental delay.[292-298] Thus, pediatric cardiac anesthesia is associated with all three risk factors, so attempting to minimize time of exposure, bundling of necessary procedures only if it will shorten the overall exposure to anesthesia, and delaying nonessential procedures to an age associated with less neurologic risk might be appropriate. Careful choice of anesthetic agents that do not act on different neuroreceptors at key time points in development might be critical.

Our current practice has evolved to minimize neurotoxicity with time under anesthesia minimized by getting help early if there is difficulty with intravenous access and having the surgeon in the room and ready to start immediately postinduction. NIRS monitors are used in all cases to optimize cardiac output and help define the need for blood transfusions. Multiple anesthetics are combined and administered in lower individual doses with the thinking that this is less toxic than a single anesthetic at a higher concentration. In all cases, a dexmedetomidine infusion is administered to decrease the dose of the other hypnotics and, when possible, regional techniques are used to reduce the total anesthesia dose.

MECHANICAL ASSIST DEVICES

Survival in children with congenital cardiac as well as pulmonary defects has improved over recent decades as a result of improved preoperative management, surgical techniques, anesthesia management, drug therapies, and postoperative management. Despite these advances, patients may still require therapies for both acute and chronic HF that are refractory to medical therapy. Mechanical support in the form of ECMO or VADs may then need to be instituted. Examples of conditions that may require support include failure to wean from CPB, acute cardiac arrest, malignant arrhythmia, and worsening myocardial function secondary to the underlying congenital defect or related to acquired cardiomyopathy. Fortunately, however, the incidence is small, with less than 2% of post-CPB patients requiring this intervention.[299] Mechanical support can thus be used as a treatment option to allow for recovery of ventricular function, as a bridge to transplant, or to support the heart in those with marginal functional reserve requiring invasive diagnostics or treatments (e.g., Williams syndrome with severe supravalvular pulmonary or aortic stenosis). As with any therapy, contraindications must be excluded before embarking on the use of a mechanical assist device. These may include extreme prematurity, severe and irreversible multiorgan failure, incurable malignancy, and preexisting neurologic devastation.[299] Anesthetic management in the use of ECMO is supportive, with management limited to assistance in the resuscitative efforts and hemorrhage associated with the cardiac surgery that was ongoing at the time of conversion to ECMO. Once the patient is on full ECMO support, ventilation is continued but at a slower rate of ventilation on the order of 10 breaths/min, with a peak pressure of 20 cm H_2O, PEEP set at 5 to 10 cm H_2O, and FiO_2 decreased to about 40%. These settings aid in the prevention of atelectasis with management of CO_2 and O_2 related to flow across the circuit membrane.

This is very different from the patient into whom a VAD is placed. Here the anesthesiologist continues to manage the patient as for routine CPB weaning. If a systemic VAD is placed, careful attention must be given to the ventricle pumping blood into the pulmonary bed because failure of this ventricle will have disastrous consequences. Thus, management tailored to unload this pulmonary ventricle is vitally important and will include inodilators in the form of phosphodiesterase inhibitors, inotropic support, and possibly even inhaled NO to decrease PVR and promote forward flow. In association with the perfusionist, intravascular volume loading is assessed and maintained for effective functioning of the VAD and thus adequate offloading of the assisted ventricle. Careful attention to pulmonary function is also vital. Adequate pulmonary toilet, recruitment maneuvers, and appropriate ventilatory parameters must be used. Bleeding is a potential complication in the implantation of the VAD and thus a clear strategy must be planned for in the form of antifibrinolytics, adequate volumes of blood and blood products, and even possibly the use of activated clotting factors (e.g., factor VII, PCCs).[300]

TABLE 78.10 Comparison of Extracorporeal Membrane Oxygenation Versus Ventricular Assist Device

Comparison Factors	ECMO	VAD
Bleeding at insertion	++	++
Sternotomy	Not required	Required
Left atrial venting	±	–
Blood product use	+++	+
Number of cannulae for biventricular support	2	4
Pulmonary support	+	–
Intravenous anticoagulation	+	±
Duration of support	Weeks	Months
Emergent support	Yes	No
Patient mobility	–	+

ECMO, Extracorporeal membrane oxygenation; *VAD*, ventricular assist device.

As can be seen in Table 78.10 differences can be appreciated between assist devices. The potential for bleeding exists at the time of insertion of both of these modalities; however, it would seem from clinical experience that because of the extensive dissection and need for sizeable ventriculotomy, implantation of a VAD (and especially bi-VAD) is more problematic. The requirements of anticoagulation to keep the ACT in the range of 180 to 200 for ECMO also may lead to ongoing and significant bleeding, especially if placed into a patient who requires support in the immediate perioperative phase. The use of an ECMO circuit with a membrane oxygenator requires ongoing intravenous anticoagulation with maintenance of the ACT in the aforementioned range. Apart from the immediate postoperative phase, patients with VAD systems can be transitioned to oral agents. A two-part therapy is recommended. Antiplatelet therapy includes aspirin or clopidogrel. The second part of the therapy will entail the use of anticoagulation with either warfarin (Coumadin) or subcutaneous low-molecular-weight heparin.[299]

Three potential disadvantages exist in the use of the VAD system. The lack of pulmonary support when using the VAD limits its use to patients whose lung function is adequate. Second, Table 78.10 illustrates that biventricular support requires two separate VAD devices, necessitating the placement of four cannulas, which may be technically difficult in a very young child. The third disadvantage is that VAD placement cannot be performed in a code situation or at the bedside as with ECMO.

Important advantages of the VAD system are the ability of patients to ambulate while on support and that VAD support can be maintained for months in contrast to the weeks only of ECMO support. Another important advantage over ECMO is that these patients will not require further venting of the LA. In patients on ECMO this is achieved by the placement of a left atrial vent at the time of sternotomy or a balloon atrial septostomy, which may require transfer to the catheterization laboratory with the possible complications associated with transport of a patient on an ECMO circuit.

Despite successful resuscitation and placement onto mechanical assist devices, morbidity and mortality remain high, with ECMO appearing to have worse outcomes. The mortality rate for ECMO in the 1990s was on the order of 47%, with survival in series published in the early 2000s not showing much improvement.[301-304] In contrast, the survival for those into whom a VAD is placed appears to be superior within the quoted series, with up to 80% of patients surviving to transplantation or being successfully weaned from support.[303,305] In the study by Blume and co-workers,[302] however, it was noted that associated CHD, and patients who are younger and smaller, have a higher mortality than those with fulminant myocarditis and cardiomyopathy.[302] Alongside survival data, the next most important marker is neurologic outcome, and it appears that this is also better in the VAD group.[306,307] Risk factors for poor neurologic outcome were once again of low weight and duration of DHCA, both of which place patients on ECMO at a survival disadvantage because patients on ECMO will be smaller and some of those who undergo DHCA for repair of congenital anomalies will require emergent ECMO support to wean from CPB or in the immediate postoperative phase.[308]

Survival predictors are important in our management of these patients. One common variable that can predict survival is the return of ventricular function between 3 and 5 days after the initiation of support.[304,308] Both of these modalities have been used successfully as a bridge to transplantation, with patients with a VAD having a greater than 80% survival to transplantation and patients on ECMO showing a less than 60% survival. Yet ECMO is used often in the infant population and in those with complex CHD, both of which are factors known to increase mortality among VAD patients.[308] The important causes of morbidity and mortality in patients on both of these modalities include cerebrovascular events secondary to either hemorrhagic or embolic phenomena, circuit-related issues (e.g., circuit thrombosis), renal failure requiring hemofiltration, sepsis, ongoing hemorrhage, and multiple-organ failure.

Although these modalities are often compared to each other, they both have unique places in the care of children with cardiac disability. ECMO has a great advantage in that it can be employed rapidly in a code situation for a patient of any age or size. In the past, size has been the limiting factor for implantation of VAD systems into pediatric patients. The Berlin Heart VAD (Berlin Heart AG, Berlin, Germany) is a pulsatile-flow device and available for use even in neonates. The system has been employed in Europe for over 20 years and has pump sizes from 10 to 80 mL.

Although this is currently the only FDA-approved VAD for children, a high incidence of adverse events such as embolic stroke, bleeding, and infections are noted.[309] This has led to the increased use of adult continuous-flow devices including the HeartMate II (Thoratec Corp., Pleasanton, CA) and HeartWare HVAD (HeartWare Inc., Framingham, MA) in children who may need it for longer periods of time, or who will potentially discharge home on the device. The Infant Jarvik VAD, a pediatric-specific continuous-flow device is currently undergoing pre-clinical testing. There are a number of other short-term VAD options that can provide additional organ support including oxygenation, hemodialysis, and plasma exchange if needed. The CentriMag/PediMag (Thoratec Corp., Pleasanton, CA) and the Jostra Rotaflow (MAQUET Cardiovascula, Wayne, NJ) are both rotary or centrifugal pumps used for short-term VAD support in multiorgan failure patients. Finally, there are percutaneous VADs now small enough to place in children. The Impella 2.5 (Abiomed Inc., Danvers, MA) is an axial VAD catheter that has been used in children as small as 22 kg. One can appreciate how these modalities complement each other, with ECMO being used acutely, and then once the patient is physiologically stable, but still requiring support, a VAD can be implanted for intermediate or long-term support. Recent data from the Organ Procurement and Transplant Network supports a survival to transplant advantage for patients with VAD (in particular, CentriMag) compared to ECMO.[310]

A newer mechanical assist device for use in children is the temporary Total Artificial Heart (TAH) system. The TAH system is indicated for use as a bridge to transplant for patients at imminent risk for death from biventricular failure. The implantation and use of this device is unique in that it requires the complete removal of the native myocardium, such that recovery without transplantation is not possible. Once the myocardium is removed, inflow and outflow pumping chambers are sown into the right and left heart vessels. Sizing requirements include patient body surface area of 1.7 m^2 or greater, echocardiographic left ventricular end-diastolic diameter of 70 mm or greater, a CT scan with an anterior-to-posterior dimension at the 10th thoracic vertebrae of 10 cm or greater, and a chest radiograph with a cardiothoracic ratio of 0.5 or greater. Smaller TAH devices may be available soon, which would allow implantation in smaller patients. This device has been used successfully as a bridge to transplant in a patient with failing Fontan physiology who later went on to receive a heart transplant.

Anesthesia for Heart and Lung Transplantation

Although perioperative management for thoracic organ transplantation is considered elsewhere in this text, the application of these procedures to children requires some specific modification. Differences include the characteristics of the candidates, preparation of these children, anesthetic management, surgical considerations, post-CPB management, and outcome. Even though some of the earliest heart transplant procedures were performed for congenital heart malformations, this indication became rare by the early 1980s. In 1984, over 60% of the few pediatric heart transplant procedures were performed in patients with cardiomyopathy, usually adolescents. In the next decade, a dramatic rise in the number of infants and young children with congenital heart malformations treated with heart transplantation resulted in a marked shift in the demographics (Fig. 78.14).[311] By 1995, over 70% of the children receiving heart transplants were younger than 5 years of age, with half of those younger than 1 year. The overwhelming majority of these infants received transplants for congenital heart malformations for which reconstructive options either had failed or were not believed to exist (Fig. 78.15).[311] The implications of this shift reach into every element of perioperative management.

Children considered for heart transplantation are more likely to have pulmonary hypertension than adults. Most adult transplant programs will not offer heart transplant therapy to patients with PVR over 6 Wood units/m^2.[312]The exclusion threshold in infants and children remains controversial. Some programs accept patients with PVR as high

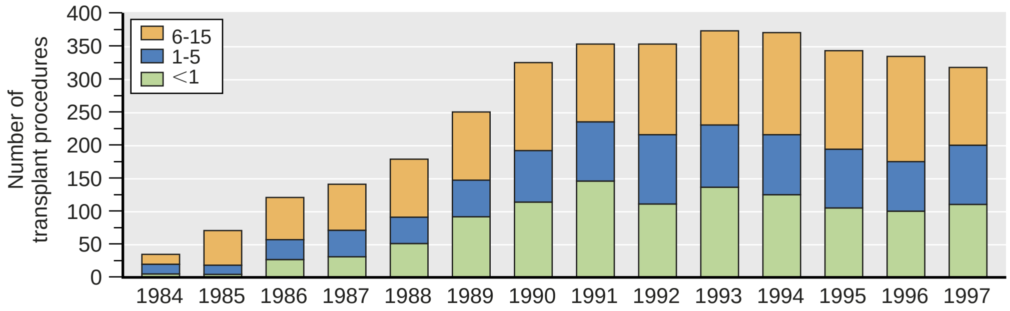

Fig. 78.14 Demographic data for pediatric heart transplantation by age. Stacked bar graph illustrates the total number and age distribution for heart transplantation in patients younger than 16 years of age. Note the rapid rise in transplant procedures performed during the late 1980s, with particular growth in the population of children 5 years of age and younger. Having peaked in the mid-1990s, the total number of transplant procedures (both adult and pediatric) has declined slightly, but the relative age proportions within the pediatric population remain relatively constant. (Data from the Registry of the International Society for Heart and Lung Transplantation, Addison, TX.)

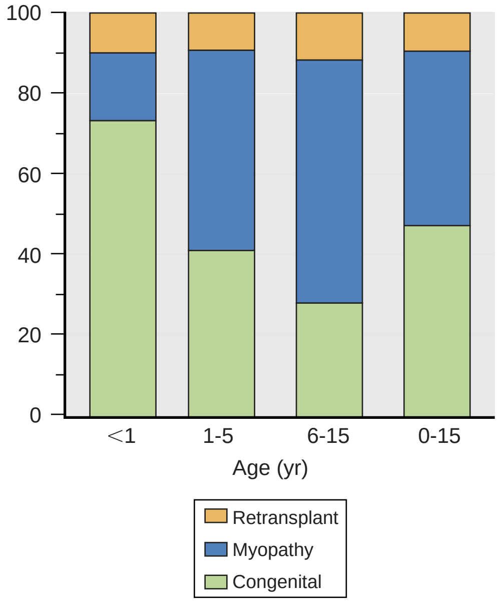

Fig. 78.15 Indication for heart transplantation in children. Over the past 2 decades, the major indications for pediatric heart transplantation were nearly equally divided between congenital malformation and cardiomyopathy. In later years, pediatric recipients with congenital malformations assumed a slight plurality as a result of shifting age demographics. As illustrated, younger children are more likely to undergo heart transplantation because of congenital malformation. (Data from the Registry of the International Society for Heart and Lung Transplantation, Addison, TX.)

as 12 Wood units/m^2, particularly if the pulmonary vasculature responds to vasodilators such as O_2, NO, calcium channel blockers, or prostacyclin.[313] Neonates are generally assumed to have elevated PVR, but outcome data from some programs suggest that the importance of this factor for postoperative outcome is substantially less in the first year of life, perhaps because the infant donor hearts, having recently undergone transitional circulation, are better prepared to cope with the right ventricular pressure load that elevated PVR imposes.[314]

The anesthetic plan for pediatric heart transplantation must accommodate a wide spectrum of pathophysiology. Recipients with congenital heart malformations benefit from the analysis of loading conditions and optimizing hemodynamics discussed previously. Although a few of these patients undergo heart transplantation because the natural history of reconstructive heart surgery poses greater risk despite reasonable ventricular function, most candidates exhibit some manifestations of impaired ventricular performance. Accordingly, they require careful titration of anesthetic agents with minimal myocardial depressant characteristics to avoid cardiovascular collapse. In this fragile population, even modest doses of opioids can be associated with marked deterioration in systemic hemodynamics, presumably by reducing endogenous catecholamine release. As with most congenital heart patients, skilled management of the airway and ventilation represents crucial elements in a satisfactory induction, particularly in the presence of elevated PVR. No matter how elegant the anesthetic plan in conception and implementation, a certain proportion of these children will decompensate on induction, necessitating resuscitative therapy. A particularly critical time is that of central line placement, when transplant patients may not tolerate the Trendelenburg position; a level table and the use of ultrasound is sufficient to place a central line.

Although orthotopic heart transplantation poses technical challenges in neonates and young infants, the replacement of an anatomically normal heart is less complex than several reconstructive heart procedures commonly performed in patients at this age. However, the need to adapt this procedure to incorporate repair of major concurrent cardiovascular malformations requires the consummate skill and creativity that remain the province of a few exemplary heart surgeons in congenital disease.[315,316]

Having withstood extended ischemic periods, heart grafts are extraordinarily intolerant of superimposed residual hemodynamic loads that may accompany imperfect vascular reconstruction. The extensive vascular repair and, particularly in older children with long-standing hypoxemia, the propensity to coagulopathy together elevate hemorrhage to a major cause of morbidity and even mortality in pediatric heart transplantation. Nevertheless, once successfully implanted, these grafts will respond to physiologic factors that stimulate growth and adaptation in the developing infant and child.[317]

Management considerations during separation from CPB and the early postoperative period are primarily focused on three pathophysiologic conditions: myocardial preservation, denervation, and PVR. Even expeditious transplant procedures usually force the heart to endure ischemic periods that exceed those encountered during reconstructive surgery. Although some researchers believe the infant heart is more tolerant of extended ischemia, these hearts will demonstrate a period of reperfusion injury, and virtually all require pharmacologic and, in some cases, mechanical support.[314] In addition, endogenous adaptive responses and exogenous pharmacologic agents that act by myocardial sympathetic activation are ineffective in the denervated graft. Because the majority of children presenting for heart transplantation exhibit some element of elevated PVR, even with isolated end-stage cardiomyopathy, the RV of a newly implanted heart is particularly vulnerable to failure.

Ventilatory and pharmacologic interventions are usually configured to exert a favorable impact on PVR and provide inotropic and chronotropic support. Once the lungs are fully expanded, we ventilate to $PaCO_2$ values in the low 30 mm Hg range using an FiO_2 of 1. Virtually all recipients receive low-dose inotropic support such as epinephrine, milrinone, dopamine, and/or isoproterenol to promote inotropy, chronotropy, and lower PVR. As mentioned previously, a major concern is RV dysfunction, hence we will generally start iNO for the immediate post-CPB period.

Most transplant centers have a specific regimen for immunosuppression to be initiated in the perioperative period. As with adults, pediatric transplant programs typically employ triple-drug immunosuppression with a calcineurin inhibitor (e.g., cyclosporine, tacrolimus), antimetabolite (e.g., azathioprine), and steroid. After an interval without rejection, some pediatric programs will taper and discontinue one or even two of these agents, particularly in neonates, in whom some element of tolerance develops.[318,319]

Survival after pediatric heart transplant is improving. The principal risk factors are age younger than 1 year and congenital heart defects. Because these factors are closely related (i.e., the vast majority of infants younger than 1 year of age undergo transplantation for a congenital heart defect), it is difficult to determine the independent effect of age. Concurrent repair of structural cardiovascular anomalies substantially increases perioperative risks for hemorrhage, residual hemodynamic loading conditions, and right-sided HF from elevated PVR. The greatest risk of mortality is found in the first year after transplant; however, infants who survive the first postoperative year have better long-term survival than other age groups.[320]. Average survival for infants is 18 years of age, which is the time at which 50% of patients are alive after transplant.[321] Average survival is 15 years for those transplanted at ages 1 to 10 years of age, and 11 years survival for those transplanted as teenagers. The sequelae of rejection and the consequences of the immunosuppression result in significant ongoing morbidity and mortality; despite advances in pharmacologic therapy, rates of acute rejection in the first year have not changed appreciably.[321]

A unique quality of neonates is that their immune system remains immature, unable to produce antibodies effectively against foreign blood cells, until approximately 12 to 24 months of age. Infants also have a poorly developed complement system. These developmental characteristics allow for transplantation of an ABO-mismatched organ into an infant, which has expanded the pool of available organs for that population. Anesthetic implications for infants who are candidates for ABO-incompatible transplant surround transfusion management—these patients should receive only ABO compatible blood products before transplant, and should not receive whole blood.[321]

Lung and heart-lung transplantation have achieved respectable operative survival rates in children.[322] They remain the only viable surgical therapy for infants and children with severe pulmonary vascular disease and selected progressive pulmonary diseases. These remain uncommon procedures in pediatrics. Lung transplantation carries the additional morbidity of obliterative bronchiolitis, a debilitating small airway disease that results in gradual deterioration in flow-related pulmonary functions over time. Despite a low operative mortality rate, 5-year survival is only 53%.[322]

Patients with transplanted hearts also present for surveillance cardiac catheterizations, biopsies, and other procedures.[299,323-325] The anesthesia plan in these patients should take into account the physiologic and pharmacologic problems of allograft denervation, the side effects of immunosuppression, the risk for infection, and the potential for rejection.[323-325] Cardiac allograft vasculopathy is the leading cause of morbidity and mortality after transplantation, leading to progressive graft dysfunction with HF, an increased risk for dysrhythmia, and the possibility of arrhythmogenic sudden death. Conventional revascularization procedures are ineffective because cardiac allograft vasculopathy is caused by intimal proliferation leaving retransplantation as the only therapeutic option.

Hyperlipidemia after heart transplantation is a common occurrence in both adults and children and is aggravated by chronic steroid therapy and other immunosuppressive agents. Statins are used with good results in controlling hyperlipidemia after transplantation and are likely to manifest inherent immunosuppressive effects. Risk factors for posttransplant renal dysfunction are the use of calcineurin inhibitors, mechanical circulatory support, prolonged inotropic support, and preexisting renal dysfunction. Newer, more potent immunosuppressive agents (e.g., tacrolimus) have led to steroid-sparing regimens late after transplantation, eliminating the detrimental effects of long-term steroid administration. Agents such as sirolimus may now be used in combination with lower levels of calcineurin inhibitors, thus minimizing long-term nephrotoxicity.

Posttransplant lymphoproliferative disorders represent a pathologic spectrum of abnormal lymphoid proliferation ranging from localized early lesions to polymorphic disease or, in some cases, monomorphic lymphomatous disease. From a clinical perspective, the most common sites of disease and presenting symptoms included the gastrointestinal tract and pulmonary systems. Patients with polymorphic disease are treated primarily by a reduction or temporary cessation of immunosuppression, along with adjunctive surgical therapy for tissue diagnosis or obstructive lesions. Most centers reserve traditional chemotherapeutic regimens for patients with nonresponsive polymorphic disease and monomorphic disease. As a result of cardiac denervation, autonomic regulatory mechanisms are not available to prevent the wide swings in a patient's hemodynamic state and the stress response is slower than usual. Cardiac parameters are significantly altered, and patients may experience a decrease in systemic blood pressure and cardiac filling pressures. Compensatory mechanisms are delayed, and reductions in cardiac output lead to decreased coronary and cerebral perfusion, especially on the background of hypertension. Drugs with direct myocardial and vascular effects are the mainstay of therapy. Most immunosuppressive agents affect hepatic and renal functions and interact with anesthetic drugs.

Anesthesia for Closed-Heart Operations

Early corrective repair in infancy has significantly reduced the number of non-corrective, palliative closed-heart operations. Corrective closed-heart procedures include PDA ligation and repair of coarctation of the aorta. Non-corrective closed-heart operations include pulmonary artery banding and extracardiac shunts such as the Blalock-Taussig shunt. These procedures are performed without CPB. Therefore, venous access and intraarterial monitoring are important in evaluating and supporting these patients. A pulse oximeter and NIRS monitors (cerebral and somatic) are invaluable devices during intraoperative management.

Ligation of a PDA is typically performed through a left thoracotomy, although video-assisted thoracoscopic techniques are increasingly common.[326,327] Physiologic management is that of a left-to-right shunt producing volume overload. Patients with a large PDA and low PVR generally present with excessive PBF and CHF. Neonates and premature infants also run the risk for having substantial diastolic runoff to the pulmonary artery, potentially impairing coronary perfusion. Thus, patients range from an asymptomatic healthy young child to the sick ventilator-dependent premature infant on inotropic support. The health of the former patient allows a wide variety of anesthetic techniques culminating in extubation in the operating room. The latter patient requires a carefully controlled anesthetic and fluid management plan. Generally, a trial of medical management with indomethacin and fluid restriction is attempted in the premature infant before surgical correction. Transport of the premature infant to the operating room can be especially difficult and potentially hazardous, requiring great vigilance to avoid extubation, excessive patient cooling, and venous access disruption. For these reasons, many centers are now performing ligation in the neonatal ICU.

A subset of premature infants with PDAs is located at institutions without cardiac surgical teams. Ligation of the PDA in these patients requires either transfer of these high-risk neonates to a center that has a team who routinely perform the procedure or the availability of a team capable of performing the procedure who is willing to travel to perform the procedure in the neonate's home neonatal ICU (NICU). Gould and associates[328] reviewed the experience with onsite and off-site ligations of a team composed of a pediatric cardiac attending anesthesiologist, a certified registered nurse anesthetist, an attending pediatric cardiothoracic surgeon and fellow, and cardiac operating room nurses. There were no anesthetic-related complications in their group. No differences were found in the incidence of perioperative complications in the procedures in the two sites. This study showed PDA ligations can be performed safely in the NICUs of hospitals lacking onsite pediatric cardiac surgical units, without incurring the risk inherent in transport of critically ill infants. In addition, patient care is continued by the neonatology team most familiar with the child's medical and social history and the patient's family is minimally inconvenienced.

Complications of PDA ligation include inadvertent ligation of the left pulmonary artery or descending aorta, recurrent laryngeal nerve damage, and excessive bleeding as a result of inadvertent PDA disruption. Placement of a pulse oximeter on the lower extremity should alert the anesthesiologist and surgeon in the case of inadvertent aortic ligation. After ductal ligation in premature infants, worsening pulmonary compliance can precipitate a need for increased ventilatory support, and manifestations of an acute increase in left ventricular afterload should be anticipated, especially if left ventricular dysfunction has developed preoperatively. PDA ligation has been performed in infants and children using thoracoscopic surgical techniques. This approach has the advantage of limited incisions at thoracoscopic sites, promoting less postoperative pain and discharge from the hospital the same day of surgery.

Coarctation of the aorta is a narrowing of the descending aorta near the insertion of the ductus arteriosus. Obstruction to aortic flow results and may range from severe obstruction with compromised distal systemic perfusion to mild upper extremity hypertension as the only manifestation. Associated anomalies of both the mitral and aortic valves can occur. In the neonate with severe coarctation, systemic perfusion depends on right-to-left shunting across the PDA. In these circumstances, left ventricular dysfunction is very common and prostaglandin E1 is necessary to preserve sufficient systemic perfusion. Generally, a peripheral intravenous line and an indwelling arterial catheter, in the right upper extremity, are recommended for intraoperative and postoperative management. In patients with left ventricular dysfunction, a central venous catheter may be desirable for pressure monitoring and inotropic support.

The surgical approach is through a left thoracotomy, whereby the aorta is cross-clamped and the coarctation repaired with an end-to-end anastomosis, patch aortoplasty, or subclavian patch. During cross-clamping, we usually allow significant proximal hypertension (20%-25% increase over baseline), based on evidence that vasodilator therapy may jeopardize distal perfusion and promote spinal cord ischemia. Intravascular crystalloid administration of 10 to 20 mL/kg is given just before removal of the clamp. The anesthetic concentration is decreased, and additional blood volume support is given until the blood pressure rises. Postrepair rebound hypertension as a result of heightened baroreceptor reactivity is common and often requires medical therapy. After cross-clamping, aortic wall stress resulting from systemic hypertension is most effectively lowered by institution of β-blockade with esmolol or α/β-blockade with labetalol.[329] Recent work indicates that patients younger than 6 years of age should receive an initial dose of esmolol 250 to 500 μg/kg, followed by an infusion of 250 to 750 μg/kg/min, depending on the blood pressure. Despite an esmolol infusion, 25% to 50% of patients have a blood pressure that is above the targeted range, requiring a second drug. Sodium nitroprusside or nicardipine is usually chosen as the second drug. Propranolol is useful in older patients but can cause severe bradycardia in infants and young children. Although it actually increases calculated aortic wall stress in the absence of β-blockade by accelerating dP/

dT (contractile force), the addition of sodium nitroprusside may be necessary to control refractory hypertension. Captopril or an alternative antihypertensive regimen is begun in the convalescent stage of recovery in patients with persistent hypertension.

The management of infants undergoing placement of extracardiac shunts without CPB centers on goals similar to those of other shunt lesions—balancing pulmonary and systemic blood flow by altering $PaCO_2$, PaO_2, and ventilatory dynamics. Central shunts are usually performed through a median sternotomy, whereas Blalock-Taussig shunts may be performed through a thoracotomy or sternotomy. In patients in whom PBF is critically low, partial cross-clamping of the pulmonary artery required for the distal anastomosis causes further reduction of PBF and desaturation, necessitating meticulous monitoring of pulse oximetry. Careful application of the cross-clamp to avoid pulmonary artery distortion will help maintain PBF. Under circumstances in which severe desaturation and bradycardia occur with cross-clamping, CPB will be required for the procedure.

Intraoperative complications include bleeding and severe systemic O_2 desaturation during chest closure, usually indicating a change in the relationship of the intrathoracic contents that results in distortion of the pulmonary arteries or kink in the shunt. Pulmonary edema may develop in the early postoperative period in response to the acute volume overload that accompanies the creation of a large surgical shunt. Measures directed at increasing PVR, such as lowering inspired O_2 to room air, allowing the $PaCO_2$ to rise, and adding PEEP are helpful maneuvers to decrease PBF until the pulmonary circulation can adjust. Decongestive therapy such as diuretics and digoxin may alleviate the manifestations of CHF. Under such circumstances, early extubation is inadvisable.

Pulmonary artery banding is used to restrict PBF in infants whose defects are deemed uncorrectable for either anatomic or physiologic reasons. These patients are generally in CHF with reduced systemic perfusion and excessive PBF. The surgeon places a restrictive band around the main pulmonary artery to reduce PBF. Band placement is very imprecise and requires careful assistance from the anesthesia team to accomplish successfully. Many approaches have been suggested. We place the patient on 21% inspired O_2 concentration and maintain the $PaCO_2$ at 40 mm Hg to simulate the postoperative state. Depending on the malformation, a pulmonary artery band is tightened to achieve hemodynamic (e.g., distal pulmonary artery pressure 50%-25% systemic pressure) or physiologic (e.g., $\dot{Q}p/\dot{Q}s$ approaching 1) goals. Should the attainment of these objectives produce unacceptable hypoxemia, the band is loosened.

Anesthesia for Interventional or Diagnostic Cardiac Procedures

Advances in interventional and diagnostic cardiac catheterization techniques are significantly changing the operative and nonoperative approach to the patient with a congenital heart defect. Common interventions in the cardiac catheterization laboratory are shown in Table 78.11. Nonoperative interventional techniques are being used instead of procedures requiring surgery and CPB for safe closure of secundum ASDs, VSDs, and PDAs. Stenotic aortic and pulmonic valves, recurrent aortic coarctations, and branch pulmonary artery stenoses can be dilated in the catheterization laboratory, avoiding surgical intervention.[330,331]

TABLE 78.11 Common Interventions in the Cardiac Catheterization Laboratory

Device Closures	Coil Embolization
SIMPLE INTERVENTIONS	
Atrial septal defect (ASD)	Decompressing veins
Ventricular septal defect (VSD)	Aortopulmonary (AP) collaterals
Patent ductus arteriosus (PDA)	Surgical shunts
Patent foramen ovale (PFO)	Coronary/atrioventricular fistulas
Balloon valvuloplasty	Balloon angioplasty
Aortic stenosis (AS)	Branch pulmonary artery stenosis
Pulmonary stenosis (PS)	Coarctation of the aorta
COMPLEX INTERVENTIONS	
Hypoplastic Left Heart Syndrome (HLHS)	
After Norwood	
Pulmonary artery stenosis	Angioplasty
Shunt thrombosis	Dilation/thrombectomy
Restrictive ASD	Balloon septostomy
Aortic arch obstruction	Angioplasty
AP collaterals	Coil embolization
Post Glenn/Fontan	
Decompressing veins	Coil embolization
Baffle leaks	Device/coil embolization
Systemic vein stenosis/thrombosis	Angioplasty/thrombectomy
Right ventricular failure	Creation of fenestration
Exercise intolerance	Closure of fenestration
AP collaterals	Coil embolization
Obstructive Fontan pathway	PA angioplasty, balloon septostomy
Transposition of Great Arteries	Balloon atrial septostomy
Tetralogy of Fallot (TOF)	
Shunt thrombosis	Thrombectomy
Pulmonary artery stenosis	Angioplasty
AP collaterals	Coil occlusion
MISCELLANEOUS INTERVENTIONS	
Severe pulmonary hypertension	Atrial septostomy
ECMO left heart decompression	Atrial septostomy
Stenosis of pulmonary veins	Balloon angioplasty stent
Stenosis/thrombosis of systemic veins	Balloon angioplasty/thrombectomy

ECMO, Extracorporeal membrane oxygenation.

These techniques shorten the hospital stay and are particularly beneficial to patients with recurrent coarctation and muscular or apical VSDs, who are at a higher risk for operative intervention. Many patients with complex cardiac defects are poor operative candidates. Innovative interventional procedures improve vascular anatomy, reduce pressure loads on ventricles, and decrease the operative risk for these patients. For example, in TOF with hypoplastic pulmonary arteries, balloon angioplasty and vascular stenting procedures create favorable pulmonary artery anatomy and reduce pulmonary artery pressure and right ventricular end-diastolic pressure. Complications are more common during interventional catheterization and include arterial thrombosis, arrhythmias (especially heart block), hemodynamic instability, embolization of devices or coils, bleeding, perforation of the major vessels or heart, and lung reperfusion injuries.[332] Complications are more common in smaller infants, particularly those younger than 6 months of age. Constant vigilance, correction of electrolyte imbalance, maintenance of acid-base status, and appropriate heparinization will mitigate some of the morbidity. Appropriate and early transfusion with deployment of rapid-response ECMO in the resuscitation of an infant in cardiac arrest improves outcome. High-risk patients undergoing diagnostic evaluation of pulmonary artery hypertension in anticipation of heart-lung transplantation also require anesthetic management. Despite the attendant high risks for the procedure in patients with suprasystemic right ventricular pressure, these patients are best managed with general anesthesia and controlled ventilation.

Anesthetic management of interventional or diagnostic procedures in the catheterization laboratory must include the same level of preparation that applies in caring for these patients in the operating room. These patients have the same complex cardiac physiology and, in some cases, greater physiologic complexity and less cardiovascular reserve. Interventional catheterization procedures can impose acute pressure load on the heart during balloon inflation. Large catheters placed across mitral or tricuspid valves create acute valvular regurgitation or, in the case of a small valve orifice, transient valvular stenosis. When catheters are placed across shunts, severe reductions in PBF and marked hypoxemia may occur. The anesthetic plan must consider the specific cardiology objectives of the procedure and the impact of anesthetic management in facilitating or hindering the interventional procedure. In general, the three distinct periods involved in an interventional catheterization are the data acquisition period, the interventional period, and the postprocedural evaluation period.

During the data acquisition period, the cardiologist performs a hemodynamic catheterization to evaluate the need for and extent of the planned intervention. Catheterization data are obtained under normal physiologic conditions—that is, room air and physiologic $PaCO_2$. Increased FiO_2 or changes in $PaCO_2$ may obscure physiologic data. Although some patients may require O_2 administration if the PBF is such that the administration of room air may lead to life-threatening hypoxia, a discussion with the interventional cardiologist is essential in the care of these children. Ideally a patient would be kept spontaneously ventilating, but this is impractical. A secured airway allows the anesthesiologist to concentrate on hemodynamic issues. Positive-pressure ventilation also reduces the risk for air embolism; the cardiologist can measure pressures during expiration to obtain the most accurate data. During spontaneous ventilation, a large reduction in intrathoracic pressure can entrain air into vascular sheaths and result in moderate-to-large pulmonary or systemic air emboli. Precise device placement is also facilitated with muscle relaxants that eliminate patient movements and controlled ventilation, thereby reducing the respiratory shifting of cardiac structures. Substantial blood loss and changes in ventricular function occur commonly during the intervention.

In the postprocedural period, the success and physiologic impact of the intervention are evaluated. Blood pressure, mixed venous O_2 saturation, ventricular end-diastolic pressure, and cardiac output, when available, are used to assess the impact of the intervention. Persistent severe hemodynamic derangement indicates the need for ICU monitoring and respiratory or cardiovascular support.

A brief description of some of the interventional procedures and the associated anesthetic implications follows. The success of these interventions will undoubtedly result in widespread availability and use over the next few years.

TRANSCATHETER TECHNIQUE FOR ATRIAL SEPTAL DEFECT CLOSURES

In the transcatheter technique for ASD closures, a collapsed double-umbrella clamshell device is loaded into a large introducer sheath placed through the femoral vein, advanced to the RA, and placed across the ASD into the left atrial chamber. Each side of the device consists of a Dacron mesh patch suspended in six spring-loaded arms that open like an automatic umbrella. Using biplane fluoroscopy and TEE, the catheter is positioned in the LA away from the mitral valve.[333] The sheath is pulled back to open the six distal arms and its Dacron mesh cover into the LA. The sheath and device are then pulled back so the distal arms contact the left atrial septum. Fluoroscopy and TEE or intracardiac echocardiography are used to confirm that the arms are on the left atrial side and do not interfere with mitral valve motion. Once adequately seated, the sheath is pulled farther back to expose the proximal side of the device and the proximal arms, which spring open to engage the right side of the atrial septum. When proper positioning is certain, the device is released.[333] Device closure of secundum ASD is the preferred therapeutic approach. Data continue to support closure of defects of small-to-moderate size (<8-20 mm) in appropriate-size patients with appropriate septal length and device diameter.[334-338] A 2012 review of percutaneous device ASD closure found a major complication rate of 1% to 2.5% (device embolization or erosion, stroke, endocarditis, tamponade, and device thrombus), and a 3.5% to 6% minor complication rate (inflammatory reactions in those with nickel allergy, arrhythmia, access-site complications).[339] Cardiac erosions and heart block can occur in patients who receive a large device for patient size, especially those who have a deficient anterosuperior rim.[340,341] Thrombus is a rare problem that can usually be treated medically, and its incidence appears to be device-dependent.[342]

TRANSCATHETER VENTRICULAR SEPTAL DEFECT CLOSURES

Most VSDs that are electively closed in the catheterization laboratory are mid-muscular or apical VSDs that are either difficult to close in the operating room or would require a left ventriculotomy. Left ventriculotomies are associated with a high incidence of left ventricular dysfunction and have been relegated to a position as the least desirable surgical option. The preferred therapeutic approach for VSD is surgical closure. Transcatheter closure of muscular VSDs can be performed safely. However, a significant incidence of complications occurs, including heart block, blood loss, and hemodynamic instability.[343,344] Device closure of membranous VSD is in early stages of investigation, and the incidence of complications remains to be determined.[345,346] The transcatheter approach requires a blade atrial septostomy and a retrograde catheter placed through the femoral artery and advanced to the LA. This catheter is pulled across the atrial septum into the RA and is used to guide a superior vena cava catheter (placed through the internal jugular vein) across the ASD into the LA, across the mitral valve, and into the LV. The VSD defect is approached from the left ventricular side. The large sheath containing the double-umbrella clamshell device prevents closure of the mitral valve, resulting in acute mitral regurgitation or, in cases in which the VSD is large or the mitral annulus small, acute severe mitral stenosis. In the latter case, systemic output is decreased and a period of severe hypotension is unavoidable. Judicious use of vasoconstrictors to maintain coronary perfusion may be required during the catheter placement, followed by volume and inotropic resuscitation after the VSD device is deployed. This highly specialized application of the clamshell device is confined to only a few pediatric centers in the United States. A 2015 review and meta-analysis comparing percutaneous versus open surgical closure of perimembranous VSD showed equivalent closure success rates between groups, and no differences in major complications (death, reoperation, need for permanent pacemaker).[347] Patients in the percutaneous closure group were older (median 12 years vs. 5 years in surgical group); blood transfusions and hospital length of stay were shorter in the percutaneous versus the surgical group.

ANGIOPLASTY OF BRANCH PULMONARY ARTERY STENOSIS

One of the most important areas of interventional catheterization has been the dilation and stenting of hypoplastic or stenotic branch pulmonary arteries. In patients with TOF with hypoplastic pulmonary arteries, pulmonary atresia, or single ventricle with surgically induced peripheral stenoses, the use of balloon angioplasty and stenting procedures creates favorable pulmonary artery anatomy and reduces the risk for subsequent surgical repairs (Fig. 78.16). Peripheral pulmonary artery stenosis is not a surgically amenable lesion and is particularly suited to catheterization and angioplasty. Balloon angioplasty is accomplished by tearing the vascular intima and media, allowing the vessel to remodel and heal with a larger diameter. The balloon is placed across the stenotic lesion so that the middle of the balloon is at the stenosis. The balloon is inflated until the waist of the balloon is eliminated. Ideally, the most stenotic lesions are dilated first to minimize the impact on PBF and cardiac output. When the balloon is inflated, PBF is reduced, right ventricular afterload is increased, and cardiac output falls. In patients with an associated VSD or ASD, right-to-left shunting and desaturation occur with balloon inflation. In patients without a shunt, acute increase in right ventricular afterload can cause systemic hypotension and right ventricular failure. The large vascular sheaths required for these procedures can introduce tricuspid regurgitation, which is poorly tolerated in patients with severe RV hypertension. Occasionally, balloon catheters must be placed across aortopulmonary shunts, significantly reducing PBF.

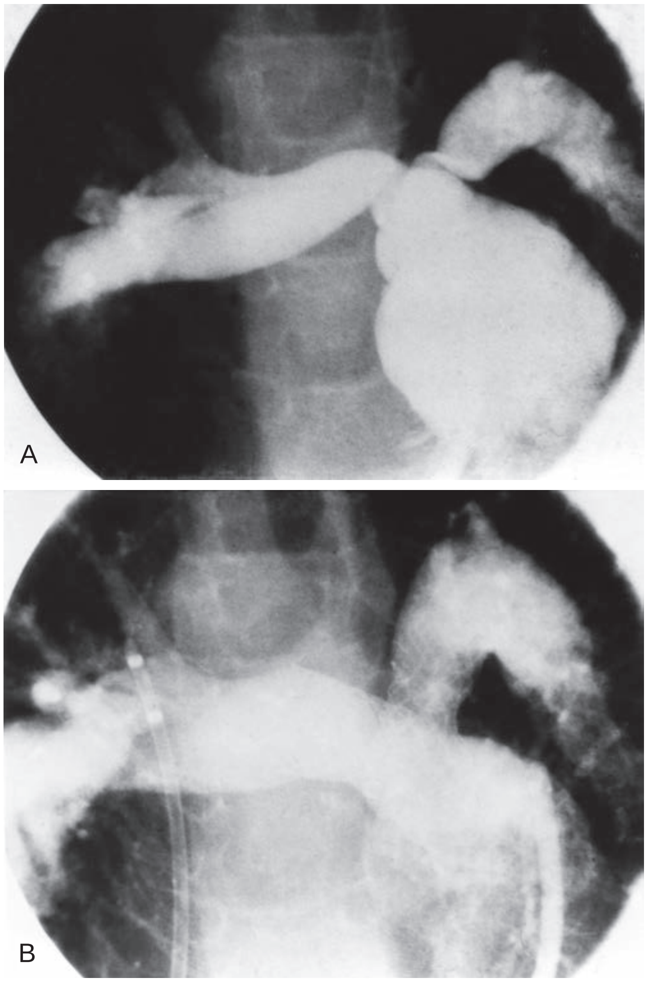

Fig. 78.16 (A) Severe bilateral branch pulmonary artery stenoses at the distal end of a conduit in a patient with pulmonary trunk atresia and ventricular septal defect. Stents were placed in the right and left pulmonary arteries. (B) Follow-up angiogram in the same projection and magnification showed marked improvement of both right and left stenoses.

The procedure is successful in approximately 60% of patients. In an early series, complications included hypotension (40%), pulmonary artery rupture (3%), unilateral reperfusion pulmonary edema (4%), aneurysmal dilation of the dilated pulmonary vessel (8%), death (1.5%), and transient postprocedural right ventricular dysfunction.[348] Improved techniques and patient selection have favorably influenced the results with superior balloon catheters and stents while significantly reducing serious complications. Anesthetic support minimizes hemodynamic compromise by anticipating changes in blood flow patterns, treating transient hypotension, and providing airway support to minimize the risks associated with pulmonary artery disruption and acute unilateral pulmonary edema.[348]

A unique group of patients are those with Williams syndrome with supravalvular aortic and pulmonary stenosis. Such patients can have multiple areas of severe branch pulmonary artery stenosis, with resultant systemic or suprasystemic right ventricular pressures and right ventricular dysfunction. Patients can also have coronary stenosis and develop subendocardial ischemia from hemodynamic disturbances in the setting of biventricular hypertrophy. The presence of supravalvular aortic stenosis, biventricular outflow tract obstruction, and coronary stenosis is associated with increased perioperative risk. Typically, such patients undergo general anesthesia with positive-pressure ventilation and recover in the cardiac ICU for angioplasty of branch pulmonary artery stenosis.[349] Care must be exercised in maintaining SVR, myocardial oxygenation, and contractility. Tachycardia and subendocardial ischemia should be avoided in the presence of ventricular hypertrophy.

BALLOON VALVULOTOMIES

Balloon valvulotomies conducted in well-compensated infants and children often can be accomplished without anesthetic support. Exceptions include neonates with critical aortic or pulmonary stenosis and patients with significant ventricular dysfunction who exhibit unstable hemodynamics. Balloon valvuloplasty is indicated in valvular pulmonary or aortic stenosis with valvular gradients more than 50 mm Hg. Balloon dilation is effective in most patients, except those with dysplastic valves (e.g., Noonan syndrome); postdilation pulmonary incompetence is anticipated and does not pose a problem in the immediate and intermediate period. Long-term prophylaxis for subacute bacterial endocarditis is needed. Only 8% of patients require repeat interventions. Typically, patients recover in the ICU and may require transfusion depending on hemodynamic stability. Valvular aortic stenosis is associated with poor surgical outcome in the neonatal period. All therapies are palliative, with a high incidence of repeat interventions, and balloon valvuloplasty is often the initial treatment. Residual obstruction or regurgitation is common after balloon dilatation and can require repeat intervention. A real risk exists for damage to the aortic valve and subaortic septum, with the consequence of acute aortic insufficiency and coronary ischemia. Hypotension and bradycardia commonly occur during valvuloplasty, and many centers have a policy of ECMO standby for these high-risk interventions in the catheterization laboratory. Ready availability of a surgical and perfusion team is crucial to a good outcome. Neonates with critical aortic stenosis often require stabilization with inotropes and prostaglandins to maintain systemic perfusion before the procedure. Balloon dilation of recurrent coarctation is often the therapy of choice in older children with recoarctation after surgery. Such patients are often hypertensive. The procedure can be performed with the patient under deep sedation or general anesthesia. In infants after Norwood palliation for HLHS, coarctation can occur in the distal arch anastomotic site. Catheters placed antegrade via the right side of the heart into the neoaorta can induce hemodynamically significant tricuspid and neoaortic regurgitation, resulting in hemodynamic instability. Careful monitoring and aggressive hemodynamic intervention result in a good outcome.

COIL EMBOLIZATION

Transcatheter methods can be adapted to occlude undesired vascular structures. Intravascular coils have been used to close PDAs, aortopulmonary collaterals, surgical systemic and pulmonary artery shunts, venous collaterals in single ventricle lesions, coronary fistulas, and some arteriovenous malformations (e.g., vein of Galen malformation). In selected instances, to minimize the risk that coils may escape to threaten vital organ perfusion, cardiologists request the use of general anesthesia with a muscle relaxant.

Depending on the lesion, patients might manifest severe cyanosis, low-output or high-output cardiac failure, or coronary ischemia. Extra care should be exercised in patients with coronary fistulas to maintain myocardial O_2 supply and reduce demand. Materials used for embolization can include surgical gel (Gelfoam), alcohol, and coils. Some of these substances can induce severe allergic reactions with hemodynamic collapse. Antibiotic prophylaxis is mandatory to prevent bacterial endocarditis. Angiography is used to demonstrate successful occlusion of the vascular structure and ascertain appropriate placement.

VALVE PROSTHESES

Transcatheter bioprosthetic valve replacement of the pulmonary and aortic valves is being performed. The pulmonary valve is a bovine jugular venous valve mounted on a balloon-expandable Cheatham platinum stent. The technique is limited by the maximum size of 22 mm of the bovine jugular venous valve. Percutaneous placement of bioprosthetic valve in the pulmonary position is a reality, and further refinement and miniaturization will lead to its application in aneurysmal right ventricular outflow tract. Current candidates for the implantation of transcatheter pulmonary valve include age of 5 years or older, weight of 30 kg or more, and a conduit diameter of 16 to 22 mm. Candidates have moderate-to-severe pulmonary regurgitation, often with RV dilation or dysfunction and mean right ventricular outflow tract gradients greater than 35 mm Hg. A single-center study comparing transcatheter PVR versus surgical PVR found that patients younger than 17 years of age had better pulmonary valve function following transcatheter versus surgically replaced valves.[350] Transcatheter PVR reduces even significant tricuspid valve regurgitation in patients with RV outflow obstruction and pulmonary regurgitation.[351] Interestingly, a prospective study of transcatheter PVR found significant increases in the size of the pulmonary artery postprocedure; this finding is of unclear significance for patient selection and long-term outcome.[352]

Transcatheter aortic valve replacement continues to be used in the management of adult patients with complex status and aortic stenosis who are not considered surgical candidates because of surgical risk. The use of these devices in pediatrics has been limited. Some authors have described the use of transcatheter pulmonary valves in the high-pressure circuit with good short-term performance. Complications of the transcatheter valve placements include wire perforation of vessels, conduit rupture, or coronary artery compression.

EMERGENT PROCEDURES

Emergent interventions such as balloon atrial septostomy to ensure adequate mixing in patients with transposition physiology and in patients who have restrictive ASD with single ventricle physiology are lifesaving and enable planning surgery at a suitable time. The procedure can be performed at the bedside with echocardiography or in the catheterization laboratory with fluoroscopic confirmation of balloon position. Access is by the femoral or umbilical vein, and the balloon catheter is advanced through the foramen ovale into the LA. The balloon is inflated with contrast and pulled back via the septum until a satisfactory ASD is created. If the procedure is successful, the left and right atrial pressures should equalize and adequate mixing should occur. Oxygenation and pulmonary venous drainage should improve. Complications include atrial perforation, laceration of the mitral or tricuspid valves and pulmonary veins, and low cardiac output state. Balloon atrial septostomy is also performed emergently in patients receiving ECMO therapy for left-sided heart decompression.

ENDOMYOCARDIAL BIOPSY

Typically, endomyocardial biopsies are performed as part of posttransplant surveillance catheterizations at regular intervals to ascertain absence of rejection in patients after orthotopic heart transplantation. Right-sided heart catheterization is usually performed by access of the right internal jugular vein, through which the long sheath and biotome are introduced. Usually five to eight samples are taken. Endomyocardial biopsies are also used to confirm a diagnosis of myocarditis or cardiomyopathy; sedation or general anesthesia is required for smaller children, although older children can undergo this procedure with local anesthesia alone. Children who undergo catheterization during a period of acute rejection are at high risk for malignant arrhythmias during endomyocardial biopsy and might require resuscitation. A clinical history suggestive of an episode of rejection includes fever, gastrointestinal disturbances, and arrhythmias. Complications include perforation, tricuspid valve damage, and the development of coronary-to–right ventricular fistulas.

CARDIAC CATHETERIZATION OF PATIENTS SUPPORTED BY EXTRACORPOREAL MEMBRANE OXYGENATION

Booth and associates[353] reported on the Boston experience of cardiac catheterization in pediatric patients supported with ECMO. Indications included assessment of surgical repair, left-sided heart decompression, myocarditis or cardiomyopathy, hemodynamic assessment, catheter interventions, and ablation of arrhythmias. The most common interventions were left-sided heart decompression in patients with left atrial hypertension, balloon angioplasty of the pulmonary arteries, and endomyocardial biopsy. The anesthesiologist coordinates safe transport of the patient on mechanical support with the perfusion and nursing team. The logistics of the transport, availability of surgeon, and blood need to be addressed before the transfer. Anesthesia is provided using isoflurane or sedatives on the ECMO circuit, and paralysis must be achieved before transport. Rest ventilation of the lungs is continued. The anesthesiologist's role is in managing a safe transport and attending to emergency mechanical, cardiorespiratory, and hematologic issues.

At present, hybrid techniques find a niche in lesions in which cardiac surgery is problematic, such as apical muscular or anterior muscular VSDs or in high-risk patients with more complex lesions in which immediate surgery is contraindicated or is associated with significant morbidity and mortality. Close collaboration is required so that a surgical approach is modified to facilitate the subsequent interventional approach. The hybrid approach has been used in the management of HLHS. Stage 1 palliation is performed by creation of an atrial septal communication and stent placement in the ductus arteriosus during catheterization to maintain ductal patency with surgically applied external right and left pulmonary artery bands or transcatheter-placed internal bands.[354,355] A modified Norwood procedure with a bidirectional Glenn anastomosis is performed with CPB during stage 2 palliation.[356] Stage 3 (Fontan operation) is performed entirely by transcatheter techniques.[357] In the current surgical climate, it seems difficult to promote ductal stenting as a method of choice but in patients with contraindications to immediate surgery this provides an attractive bridge.[358]

Adult Congenital Heart Disease

EPIDEMIOLOGY AND CLASSIFICATION

The care of adults with CHD is a new and exciting frontier in medicine. Adult congenital heart disease (ACHD) represents a large spectrum of clinical entities ranging from mild to severe and palliated to corrected, with no or multiple adult comorbidities. The incidence of CHD is estimated to be 3 to 6 cases per 1000 live births. Approximately 85% of these patients can be expected to reach adulthood.[359] The prevalence of CHD is rising in both children and adults, with adults representing the largest group.

At the Bethesda conference in 2001, patients with ACHD were categorized into groups of simple, moderate, or great complexity based on medical diagnosis.[359] Anesthesiologists should be aware of the Bethesda task conference recommendations for ACHD in terms of distribution of care for these patients. It is recommended that patients with CHD of great complexity be regularly seen at tertiary care centers that specialize in ACHD.

CONSIDERATIONS IN THE CARE OF PATIENTS WITH ADULT CONGENITAL HEART DISEASE

Adults with CHD may present with unique anatomy or physiologic sequelae not otherwise encountered in pediatric patients with CHD. Some patients with ACHD may have had palliative repairs no longer primarily employed for specific diseases today, such as the Mustard or Senning procedure for dextro-transposition of the great arteries (d-TGA). In addition, these patients may not have complete awareness or access to information on medical treatments completed when they were a child. As the number of patients with ACHD increases, so do the chances an anesthesiologist will need to care for one of these patients in an emergent situation. In general, practitioners would want to gather as much information as available in regard to the details of the patient's medical history, surgical repairs, and current functional status.

General considerations include presence of arrhythmias, hypoxemia, pulmonary hypertension, ventricular dysfunction, shunts, thrombosis, and need for antibiotic prophylaxis. Arrhythmias are one of the most common sequelae in adults with CHD. Common arrhythmias occur as the result of atrial dilation and include atrial fibrillation or flutter, which may or may not be hemodynamically significant. A right bundle branch block pattern of the QRS segment of the ECG is common after repair of TOF. In the absence of lung disease, hypoxemia results from a decrease of PBF, either due to obstruction or right-to-left shunting. Strategies to avoid further hypoxemia include adequate hydration, ventilation, and pulmonary perfusion while decreasing PVR or O_2 consumption. It is prudent to determine patient baseline SpO_2 as a reference for the anesthetic. Many patients with ACHD with chronic hypoxemia may require hematocrit values greater than 45% to allow for adequate O_2 delivery; O_2 carrying capacity may be maximized by the administration of packed RBCs. Along with cyanosis, the presence of polycythemia in these patients increases their thromboembolic risk.

The presence of pulmonary hypertension should always be considered when caring for patients with ACHD. Chronic volume overload to the pulmonary vascular bed creates hypertrophy of the arterioles with resultant pulmonary hypertension. Common defects where pulmonary hypertension may be found in childhood include shunt lesions, which, if untreated, result in pulmonary vasoocclusive disease. When hypoxemia is present with these conditions, a high level of suspicion for pulmonary hypertension and possibly Eisenmenger syndrome is necessary. The anesthesiologist should always have a high level of suspicion for the presence of ventricular dysfunction in patients with ACHD. Many CHD defects place a volume or pressure load on the heart that over time may lead to dilated or hypertrophied performance. The careful titration of induction and maintenance agents that maintain ventricular performance is warranted in providing anesthesia care. Shunts of varying size and location may be created in the care of hypoxic patients with CHD in an effort to increase PBF. In many cases, patients rely on the patency of these shunts to supply the lungs with blood and their occlusion could be catastrophic. Likewise, thrombosis of various shunts or cardiac chambers may occur related to altered patterns of blood flow. Therefore, specific anticoagulation strategies may be required to ensure blood flow. The American Heart Association has provided updated guidelines regarding recommendations for prophylaxis against infective endocarditis, and specific guidelines may be found in this chapter (Table 78.12).

TABLE 78.12 Infective Endocarditis Prophylaxis

		SINGLE DOSE 30-60 MIN BEFORE DENTAL PROCEDURE	
Situation	**Drug**	**Adults**	**Children**
Oral	Amoxicillin	2 g	50 mg/kg
Unable to take oral medication	Ampicillin or	2 g IM/IV	50 mg/kg IM/IV
	Cefazolin/ceftriaxone	1 g IM/IV	50 mg/kg IM/IV
Allergic to penicillins/oral	Cephalexin or	2 g	50 mg/kg IM/IV

Vancomycin is an alternative for patients who are unable to tolerate a β-lactam or when the infective agent is considered to be methicillin-resistant *Staphylococcus aureus*.

SPECIFIC LESIONS WITH UNIQUE CONSIDERATIONS FOR ADULT CONGENITAL HEART DISEASE

Tetralogy of Fallot

TOF consists of four defects of varying physiologic significance: malignant type VSD, varying degrees of right ventricular outflow tract obstruction, right ventricular hypertrophy, and an overriding aorta. The typical clinical significance of this pattern of cardiac anomalies is that of hypoxia as a result of decreased PBF. In the early stages of treatment of TOF the systemic–pulmonary artery shunt (Blalock-Taussig shunt) was used to allow the child to grow, followed by a definitive repair later in life. Many patients up until the 1970s may have had classic Blalock-Taussig shunt or central shunts performed. A mBTS is used today for patients who require augmented PBF but who are not candidates for early complete repair. Most infants undergo complete repair in the first year of life; on occasion, a degree of pulmonary stenosis protects the lung from overcirculation of blood from the VSD while allowing adequate PBF for growth, and these patients may ultimately not require surgical repair.

Adults with TOF may have had any of these potential surgical repairs. The type of repair completed and functional status of the repair should be ascertained. The most common long-term complication after TOF repair is pulmonary insufficiency; cardiac MRI is utilized to follow right ventricular volumes over time to aid in the timing of surgical repair or pulmonary valve replacement.[360] Elevated jugular venous pressures and hepatomegaly should alert the anesthesiologist to right ventricular failure. Other complications of TOF repair include arrhythmias of right ventricular origin or right bundle branch block patterns on the ECG, particularly in the case of previous ventriculotomy. Cyanosis in these patients suggests inadequate PBF.

Fontan Circulations

In the early1970s, Fontan and Kreutzer preformed a procedure in a patient with tricuspid atresia in an attempt to separate the PBF from the systemic circulation[361]; known now as the Fontan procedure, or total cavopulmonary anastomosis, the goal is to divert deoxygenated venous blood return directly and passively from the systemic venous circulation to the lungs, allowing the single ventricle to pump oxygenated blood to the systemic circulation. This principle of blood diversion is now applied to many types of functionally single-ventricle patients, usually as a series of two to three-staged procedures. Currently, Fontan operations for single-ventricle patients are performed on patients between 2 and 4 years of age, resulting in separation of pulmonary and systemic circulations. However, occasionally, adults present without having undergone a complete separation of circulations. Such patients have variable levels of cyanosis and ventricular dysfunction.

Even with the completion of total cavopulmonary anastomosis, many patients experience a decreased survival beyond 15 years after surgery. Impaired systolic and diastolic ventricular function as well as increased PVR contribute to mortality, and HF therapies to treat two-ventricle patients may not be efficacious in one-ventricle patients.[362] Common causes of death after Fontan procedures include thromboembolism, HF, protein-losing enteropathy, and arrhythmias.[363] When caring for adults with Fontan physiology, the anesthesiologist should be mindful of conditions that may further impair oxygenation and myocardial function. PBF is passive, and any condition that increases PVR, or decreases systemic venous volume, will be poorly tolerated. These patients may also be very sensitive to myocardial depressants. In addition, the initial Fontan procedures included a direct baffle of the atrium to the pulmonary artery, but this was later modified because of complications from atrial dilation and the resulting arrhythmias. Fontan procedures are currently extracardiac, to minimize atrial arrhythmia. Expected O_2 saturation in a patient with Fontan physiology is at least 95%, though it may be lower in a patient with Fontan failure. Chronic anticoagulation for patients who have previously demonstrated, or are at presumed high risk for, thromboembolism is common and must be considered preoperatively.

Transposition of the Great Arteries

TGA occurs when the aorta arises from the anatomic RV and the pulmonary artery arises from the anatomic LV. In classic d-TGA the two circulations are in parallel and require mixing to be compatible with life. In the 1980s, surgical management of TGA consisted of atrial-level switch procedures—the Mustard or Senning procedure—in which venous return to the heart was redirected at the atrial level though a baffle system. Therefore, highly oxygenated pulmonary venous return was redirected to the RV, which pumped to the aorta and systemic circulation. Systemic deoxygenated blood was directed to the LV, which pumped the blood through the pulmonary artery to the lungs for oxygenation. Long-term complications of this strategy include atrial dilation from baffle obstruction or leak with resultant arrhythmias, sinus node dysfunction, or sudden death. Particularly problematic complications included the systemic right ventricular dysfunction, AV valve regurgitation, subpulmonary stenosis, and pulmonary hypertension. Today, the arterial switch operation is preferred, in which the aorta with the coronary arteries are attached to the LV and the pulmonary artery is attached to the RV. Complications from the arterial switch operation include regurgitation of the neoaortic valve, myocardial ischemia from coronary ostial stenosis, right or left ventricular outflow tract obstruction, residual intracardiac shunting, and left ventricular dysfunction.

Pediatric Cardiac Electrophysiology

DIAGNOSTIC EVALUATION

Cardiac Event Monitoring

Most patients with cardiac arrhythmias present with infrequent or episodic symptoms. These symptoms may include chest pain, palpitations, syncope, and presyncope. Transtelephonic electrocardiographic event monitors may yield documentation of the arrhythmia because they are portable and patient activated.[364]

Insertable Cardiac Recorders

Insertable loop recorders implanted subcutaneously allow continuous rhythm monitoring that is stored either when manually activated by a patient or parent or automatically when high or low rate parameters are met.[365] These insertable loop recorders have value in correlating arrhythmias with symptoms when noninvasive means do not make a diagnosis. Typically, loop recorders are inserted under general anesthesia as an outpatient procedure and cause minimal pain.

RADIOFREQUENCY ABLATION OF ACCESSORY PATHWAYS

Radiofrequency ablation is a nonsurgical approach designed to eliminate atrial or ventricular reentrant tachyarrhythmias. The technique requires pathway mapping and precision ablation of the aberrant pathway, using a radiofrequency ablation catheter. Catheter ablation is offered to patients with refractory arrhythmias that are bothersome and the focus or pathway is amenable to ablation. Supraventricular tachycardias (SVTs) have an incidence of 1 in 250 to 1000 children and usually present later in childhood.[366] Up to 50% of adults with CHD develop SVT.[367] Although right-sided pathways are easier to access, left-sided pathways that require a transseptal puncture have a better cure rate.[368] In pediatrics, the electrophysiology catheters are introduced by femoral venous catheterization and the tips are positioned in the right atrial appendage, the bundle of His area, right ventricular apex, and the coronary sinus. Occasionally, right internal jugular venous access is used for placement of the coronary sinus catheter. Rapid atrial pacing and, occasionally, an isoproterenol infusion are required during the mapping procedure to induce the arrhythmia. An ablation catheter is used to map the substrate, and, subsequently, the pathway is ablated using radiofrequency energy (300-750 kHz). In complex cases or in cases with pathways in the vicinity of the AV node, cryotherapy is used to limit damage to the AV node. Cryotherapy permits a slower burn, and the ability to stop the ablation if transient AV block or lengthening of the PR interval occurs. General anesthesia is required for ablation procedures in children, as unexpected patient movement may result in catheter dislodgment and damage to normal conducting tissue.

Anesthetic drugs and techniques should aim to maintain circulating catecholamines and avoid suppression of arrhythmogenesis, to aid in identification of the aberrant pathway. Total intravenous anesthesia with propofol or a low-dose volatile anesthetic are equally satisfactory options. Data suggest that modern inhaled anesthetics such as isoflurane and sevoflurane have no significant effects on cardiac conduction in children with SVT and are therefore suitable options.[369,370] There is conflicting evidence on desflurane with more recent data suggesting it may block AV conduction and therefore may not be a good anesthetic in these cases.[371] An increased incidence of postoperative nausea and vomiting (PONV) is reported after these procedures, which is not only distressing but may produce bleeding from the access sites. Both low-dose propofol infusion and low-dose volatile anesthetic may be used along with the bispectral index monitor to maintain a lighter level of anesthesia. To minimize the risk of PONV, two classes of antinausea medications should be administered. Placement of an arterial line is needed for rapid atrial pacing and isoproterenol during the mapping procedure, both of which can cause significant hypotension. Medications that suppress conduction or decrease sympathetic tone, including dexmedetomidine, should be avoided until the end of the procedure.

Severe postablation cardiomyopathy has been described but is very unusual. Presumed causative factors include underlying cardiomyopathy from frequent episodes of SVT, and myocardial O_2 imbalance caused by prolonged periods of rapid atrial pacing and isoproterenol infusions. Other procedure complications include radiation exposure, tamponade, pericarditis, groin hematoma, arterial thrombosis, AV block, systemic embolization, coronary artery dissection, trauma to the mitral and tricuspid valves, and endocarditis.

Intraatrial Reentrant Tachycardia

Intraatrial reentrant tachycardia (IART) is the most common arrhythmia in CHD and is associated with significant morbidity and mortality. The incidence of IART is highest in patients who have undergone Fontan and atrial switch operations because of atrial incisions, sutures lines, and dilation, and fibrosis caused by long-term hemodynamic changes.[367] Therapeutic options for IART include antiarrhythmic medications, radiofrequency catheter ablation, cryoablation, surgery, and pacing. The Pediatric and Congenital Electrophysiology Society and the Heart Rhythm Society have published comprehensive guidelines for arrhythmia management in ACHD.[372] Careful choice of anesthetic, monitoring, and early management of low cardiac output states, especially in patients with single-ventricle physiology, are important. Prolonged periods of arrhythmia induction during mapping can reduce cardiac output and necessitate inotropic therapy. Cardiac ICU may be indicated for postoperative recovery. Although acute success rates are high at 90%, arrhythmia recurrence is problematic in this population occurring in 34% to 54% of patients. Fontan physiology and older age are risk factors for recurrence.[367,373] As more patients with CHD survive into adulthood, the incidence of both permanent IART and atrial fibrillation are increasing.[374]

Intraoperative cryoablation within the RA for patients with IART or LA for atrial fibrillation using preoperative and intraoperative mapping can be used successfully. Atrial antitachycardia pacing is an option to terminate treatable tachycardias; a single-center cohort study demonstrated that this technology decreased the need for cardioversion rate in patients with CHD.[375] Atrial antitachycardia pacing has reduced efficacy in patients with L-TGA. In patients who are either unsuitable candidates for catheter ablation or in whom ablation has been unsuccessful, surgical ablation may be successfully combined with repair of CHD.

Arrhythmias and Sudden Cardiac Death

Certain cardiomyopathies and channelopathies are associated with an increased risk for sudden cardiac death resulting from lethal arrhythmias. The patient usually has a history of syncope, near-syncope, or aborted sudden death. Such patients present for insertion of automated internal cardioverter-defibrillators (AICDs) for either primary or secondary prevention.

IMPLANTATION OF PACEMAKERS AND DEFIBRILLATORS

Pacemakers are indicated for complete heart block or sinus node dysfunction with symptomatic bradycardia and hemodynamic decompensation. Children usually require general anesthesia with endotracheal intubation. It should be noted that the anesthetic can be associated with worsening bradycardia. Transthoracic pacing pads are applied before induction of anesthesia, and an isoproterenol infusion should be available in case its needed for chronotropy. External transthoracic, esophageal, or emergent transvenous pacing may be necessary until placement of a permanent pacing device is achieved. In small children the pacemaker generator is typically placed in the upper abdomen, and in older children and teenagers it is placed in the subclavicular region. Epicardial leads are used in small children because of inadequate size of the veins and in those in whom transvenous access to the heart is impossible (e.g., the Fontan circulation). Epicardial pacemaker placement usually is performed by a cardiac surgeon, with electrophysiologists readily available to program the device. Adequate peripheral venous access is mandatory in the event of major hemorrhage, and blood should be readily available. A mode of monitoring mechanical capture of electrical pacing activity is also necessary and can include invasive arterial monitoring or pulse plethysmography. Transvenous pacing can be achieved in the operating room with surgical backup or in the cardiac catheterization laboratory by the cardiologists. In the latter situation it is important to address the need for surgical backup during case planning.

AICDs are placed for life-threatening ventricular arrhythmias, which include LQTS, hypertrophic cardiomyopathy, and arrhythmogenic right ventricular dysplasia. Of note, the device is tested after placement, with induction of ventricular fibrillation. It is absolutely essential to have external modes of defibrillation available, as well as antiarrhythmics such as amiodarone, magnesium, and lidocaine, in the event of device failure. These devices are placed with the patient under general anesthesia with endotracheal intubation and controlled ventilation. Invasive arterial pressure monitoring is typically used. Adequate analgesia can be provided with local infiltration with local anesthetics and short-acting intravenous opioids. Patients are admitted overnight with telemetry monitoring. Appropriate antibiotic therapy is provided for a 24-hour period.

Advances in Resynchronization Therapy

Bundle branch block or interventricular conduction delay often accompanies HF and some forms of CHD, either preoperatively or postoperatively, and may result in ventricular dysfunction caused by asynchronous myocardial contraction. Biventricular pacing is an attempt to resynchronize ventricular contraction by pacing both ventricles, thereby improving overall ventricular function. In patients with left bundle branch block, cardiac resynchronization therapy counteracts the underlying electrical and mechanical dyssynchrony, leading to improved contractility, function, exercise tolerance, and quality of life. Multisite pacing, involving intraoperative placement of atrial and ventricular unipolar epicardial temporary pacing wires, improves cardiac index and systolic blood pressure in the immediate postbypass period.[376] Multisite, temporary pacing may not be indicated or necessary to improve function in low-risk, biventricular repairs[377]; however, despite long-term outcome data, multisite pacing has become standard in many circumstances, including single-ventricle physiology, redo-procedures, or in patients at high risk for morbidity and mortality.

Right bundle branch block is a common outcome after surgery for congenital heart lesions. Right ventricular pressure, volume loading, or both also may be present, with attendant right ventricular enlargement and dyskinesis. Dual-chamber pacing decreases the QRS duration and increases cardiac index; the pacing site producing the most narrow QRS duration is of most benefit.[378,379]

Anesthesia for Noncardiac Surgery

INFECTIVE ENDOCARDITIS PROPHYLAXIS: AMERICAN HEART ASSOCIATION GUIDELINES

Guidelines for infective endocarditis prophylaxis were updated by the American College of Cardiology and the American Heart Association in 2008. A detailed discussion of the changes is beyond the scope of this chapter.

Procedures for which prophylaxis for infective endocarditis is recommended include the following[380]:

- Dental procedures involving manipulation of the gingival tissue or periapical region of the teeth or involving perforation of the oral mucosa
- Respiratory procedures involving incision of the respiratory mucosa
- Procedures involving infected skin, skin structure, or musculoskeletal tissue

Prophylaxis is no longer routinely recommended for gastrointestinal and genitourinary procedures. For elective procedures, coexisting enterococcal urinary tract infections should be treated before genitourinary or gastrointestinal procedures; for emergent procedures, in patients at highest risk for infective endocarditis, prophylaxis can be considered.

Conditions for which prophylaxis is recommended for dental procedures include the following (see Table 78.12):

- Prosthetic cardiac valve
- Previous infective endocarditis
- Unrepaired CHD, including palliative shunts and conduits
- Completely repaired CHD with prosthetic material or device within the first 6 months after the procedure
- Repaired CHD with residual defects at the site or adjacent to the site of a prosthetic patch or device
- Cardiac transplant recipients who develop cardiac valvulopathy

These are guidelines only, and it is prudent practice to consult the child's cardiologist in order to create an individualized plan based on the child's condition, operative procedure, and risk for bacteremia.

MAGNETIC RESONANCE IMAGING OF THE HEART

A major advantage of MRI is the ability to assess the volume and mass of asymmetric ventricular shapes, especially the RV. The American Society of Anesthesiologists (ASA) has published a practice advisory on anesthetic care for MRI.[381] Apart from the usual considerations of providing general anesthesia in a remote location, the anesthesiologist must be prepared to provide resuscitative care when working in a magnetic field necessitating the use of magnet-safe equipment. Patients with implanted devices and hardware need to be assessed to ensure magnet compatibility and safety. Generally, pacemakers, implanted defibrillators, and aneurysm clips are contraindications to MRI. Coils, stents, and other surgical clips produce interference and imaging artifact but do not constitute a threat to patient safety. In a majority of patients, the scan can be performed as an outpatient procedure.

Patients who are younger, uncooperative, or claustrophobic require sedation or general anesthesia. Good image quality, angiography, and delayed enhancement imaging are aided by breath holds, which may last for more than one minute and require preoxygenation. Typically, if breath holds are required, general endotracheal anesthesia is required and an anesthesia provider is present in the room. However, radiologic advances have allowed many centers to use "free breathing" protocols to avoid the need for breath holds and therefore general anesthesia.[382,383] Such protocols acquire multiple images, then use an algorithm that eliminates the artifact created by respiration. Radiologists are increasingly cognizant of the potential risk of general anesthesia in young children and are adapting protocols to avoid the need for general anesthesia when possible.[384]

Irrespective of anesthetic technique, it is mandatory to maintain continuous monitoring of heart rate, pulse oximetry, capnography, and noninvasive blood pressure. In the event of hemodynamic compromise, the patient should be removed from the MRI scanner into a safe environment where resuscitation equipment can be safely used. With the development of compatible catheters and devices, MRI is a useful tool in minimizing x-ray exposure, particularly in patients whose CHD necessitates numerous catheterization procedures. Cardiac MRI may be used in combination with fluoroscopy in the catheterization suite to decrease radiation exposure and improve soft tissue visualization in patients with CHD.[385]

Offsite Anesthesia in Cardiac Surgery Patients

Patients with cardiac disease are no different from any other group of patients who require procedures or investigations in areas outside the operating room. Therefore, anesthesiologists should always be prepared for any eventuality and follow guidelines such as those set out by the ASA. This discussion excludes procedures performed in the cardiac catheterization laboratory as this has been addressed elsewhere. The nature of congenital cardiac surgery will result in a number of patients requiring emergent chest exploration for hemorrhage or to relieve tamponade, or for ECMO cannulation, all of which may take place in the ICU setting. It is obvious that we cannot predict with certainty which patients will have problematic postoperative courses, but the practitioners who have participated in the operative phase will gain an accurate sense of which patients may require possible further exploration or surgery. Accordingly, it is best to plan ahead, and prepare for worst-case scenarios. It is imperative that enough blood and blood products are available to perform surgery at any given time. Successful treatment of emergency situations depends on a team approach to patient care, and thus surgeons, anesthesiologists, intensivists, perfusionists, and operating room nurses must be immediately available. When the decision is made to perform a procedure within the ICU, speed of preparation is of the essence. Drugs, electrolytes, and infusions must be readily available. Emergent preparation includes ensuring that blood is checked, a warmer is ready for use, emergency drugs are present, and the code cart (with internal paddles) is available. The anesthesiologist's role is one of facilitation of the entire procedure including sedation, airway management, patient positioning, preparing the blood, and continuing ongoing volume and pharmacologic resuscitation.

The premature infant with a PDA poses an interesting management problem to cardiac surgery teams because frequently these ill neonates are at hospitals far from major centers where the team is normally assembled. As referenced in an article by Gould and associates,[328] teams have been performing these ductal ligations with great success at hospitals remote from their "home" hospitals. The philosophy is to take the cardiac team to the neonate instead of having these fragile infants transported. In this article, neonates operated on in the "home" hospital NICU were used as the controls, and it was found that the success and complication rates were comparable in the two groups. Thus, from an anesthetic perspective, travel with a full complement of airway equipment and drugs, as described earlier, with packed red cells being made available at the host hospital. The anesthetic regimen for this procedure comprises a high-dose opioid, muscle relaxant, antibiotic, and a continuation of any preoperative vasoactive infusions. We have found that this is a stable and well-tolerated anesthetic regimen.

The requirement for anesthesia services is ever-widening, and in patients with pediatric heart disease this is also the case. Thus, the patients will require radiologic investigations, including CT, MRI, and nuclear medicine scans; interventional radiology procedures; and gastrointestinal procedures, among others. Before discussion of the patient and the anesthetic, it is important for the practitioners to have a thorough knowledge of the environment into which they are taking the patient with regard to magnetic fields, closest code cart, and the ability to get help quickly if needed. Without going into the specifics of every potential clinical scenario, a few basic points are discussed.

As with any anesthetic procedure, a thorough preoperative evaluation is vital. Most patients with pediatric heart disease have long and complex histories, so this assessment should include a detailed description of their cardiac status, including prior surgeries, catheterization findings, and associated conditions (e.g., neurocognitive function, pulmonary status, renal function). Depending on the patient's underlying condition a recent echocardiogram will give very important clinical details related to overall function, valve pathology, presence or absence of intracardiac shunt, patency of surgical shunts, and presence of pericardial fluid. Although this may be ideal, often the echocardiographic examination may be remote from the anesthetic encounter and thus the clinical history and examination are important. Patients who have had a heart transplant should have a relatively recent echocardiogram, as it will provide vital information that may indicate worsening function in an otherwise asymptomatic patient.

Nothing-by-mouth guidelines deserve special consideration. Many congenital cardiac patients have physiology in which dehydration may be deleterious (e.g., single-ventricle, presence of surgical shunts, unrepaired TOF). In these patients, it is important to allow and encourage oral hydration up until 2 hours before the planned procedure; if this is not possible, intravenous fluids must be used. The anesthetic course will depend on the duration of the planned procedure, the patient's physiology (i.e., spontaneous vs. controlled ventilation), airway management (natural vs. laryngeal mask airway vs. endotracheal tube airway), anesthetic maintenance, travel to and from the procedural area, and maintenance of the patient's temperature. Before leaving the induction area the anesthetic team must be prepared for airway misadventures and even a code situation; thus, the team must travel with auxiliary airway equipment and resuscitative drugs. The very number of these different venues may make it difficult to have an anesthesia machine present in each; however, an anesthetic cart with additional airway equipment, intravenous materials, and resuscitative drugs should be present. The anesthetic that is delivered may vary among practitioners and institutions, but the common details of importance are a thorough knowledge of the patient and the ability to treat expeditiously should any difficulty ensue in a remote venue.

Acknowledgment

The editors, publisher, and returning author Dr. William J. Greeley, would like to thank Dr. Aruna T. Nathan and the late Dr. Chad C. Cripe for their contributions to this chapter in the prior edition of this work. It has served as the foundation for the current chapter.

Pediatric and Neonatal Critical Care

TODD J. KILBAUGH, MAURICE S. ZWASS, and PATRICK ROSS

KEY POINTS

- Congenital heart disease causes significant alterations in oxygenation, perfusion, and myocardial function after birth, and it can be categorized into hypoxic and normoxic lesions.
- The overall goal of therapy in shock is to treat the underlying cause, return adequate oxygen delivery to the tissues, and remove metabolic products that developed during anaerobic metabolism. It appears that the faster the body returns to adequate perfusion, the better the overall outcome.
- One of the specifics for neonatal resuscitation is the recommendation of positive pressure ventilation (PPV) with room air, unless chest compressions or medications are needed during the resuscitation, then the recommendation is still for PPV with 100% oxygen.
- Pediatric cardiac arrest is not a rare event. At least 16,000 American children (8-20 per 100,000 children per year) suffer a cardiopulmonary arrest each year.
- The four distinct phases of cardiac arrest and cardiopulmonary resuscitation (CPR) interventions are: (1) prearrest, (2) no-flow (untreated cardiac arrest), (3) low-flow (CPR), and (4) post-resuscitation and arrest.
- Acute respiratory distress syndrome (ARDS) diagnostic criteria have been revised recently and are now the Berlin Definition, where ARDS is separated into three mutually exclusive categories based on the degree of hypoxia. Mild is $PaO_2/FiO_2 = 201$ to 300 with positive end-expiratory pressure (PEEP) > 5, moderate is $PaO_2/FiO_2 = 100$ to 200 with PEEP > 5, and severe is $PaO_2/FiO_2 < 100$ with PEEP > 10.
- Traumatic brain injury (TBI) is composed of two components—an initial primary injury owing to direct mechanical deformation of brain parenchyma and a subsequent secondary injury that can develop over hours to days. Secondary injury may be the result of multiple mechanisms including ischemia, excitotoxicity, metabolic failure and eventual apoptosis, cerebral swelling, axonal injury, and inflammation and regeneration.
- A vascular occlusive crisis in the lungs leads to acute chest syndrome (ACS). Acute chest syndrome is the leading cause of death and the second most common complication in sickle cell disease.
- Tumor lysis syndrome is a metabolic crisis precipitated by acute lysis of a large number of tumor cells. Serum uric acid, potassium, and phosphate concentrations are elevated. The elevated phosphate concentrations cause hypocalcemia.
- The role of family in the pediatric intensive care unit (PICU) has evolved over time, and the inclusion of family in the care of their child is now recognized as an important part of critical care.
- Accidents and trauma are the leading causes of death in children 1 to 14 years of age.

Relationship Between the Intensive Care Unit and the Operating Room

The field of pediatric intensive care may have originated from anesthesia, but these areas have grown apart over time. Due to the extensive training, there are few individuals who cover both disciplines. With more complex patients, it is likely that care will occur both in the operating room and the intensive care unit (ICU). There needs to be excellent communication between the ICU and operating room clinicians to ensure a seamless transition of care. Many institutions require an attending to attending handoff between the ICU and anesthesia for each case. It is important that this occurs in the preanesthetic as well as the postanesthetic setting. Information regarding current ICU therapy response can simplify a potentially difficult anesthetic. Similarly, understanding the operative and anesthetic course will guide the next several days of management. A complete anesthesia sign-out includes pertinent past medical history, allergies, ease of mask ventilation, induction agents, ease of intubation, decisions regarding extubation, venous and arterial access, blood products, fluid totals, inotropic agents, medications delivered including timing of antibiotics, complications, laboratory values, and most recent blood gas. This information may be available in the anesthetic record; however, a short verbal summary by the anesthesiologist provides a greater amount of practical detail.

Family Partnered Care in the Pediatric Intensive Care Unit

The family is an important part of the critical care team and needs to be included in shared decision making. In pediatric hospitals, families participate in multidisciplinary rounds with their nurses, respiratory therapists, pharmacists, and physician caring for their child. This does not require more time than traditional rounds and it does not compromise teaching.[1] There has been a significant push to increase family participation in both pediatric and adult ICUs. Family engagement is part of the ICU Liberation ABCDEF Bundle that is directed and supported by the Society of Critical Care Medicine. A great amount of information is available at www.iculiberation.org. An international multidisciplinary team of experts in neonatal, pediatric and adult critical care recently published Guidelines for Family Centered Care.[2] The guidelines address the need for family presence in the ICU, the need for family support beyond the ICU; goals for communication, use of consult services such as Palliative Care and Ethics, and a means to address the operational and environmental issues in ICUs that prevent family engagement. We see significant family satisfaction with participation in rounds and we believe it likely benefits the team and patient as well.[3-5] We anticipate a point in the future where we do not need to prove to anyone the need to have family involvement.

Giving the family a greater presence in the ICU with more responsibility and autonomy in decision making can increase their anxiety and distress. In addition to the potential development of posttraumatic stress disorder (PTSD) in our patients,[6-8] parents of children admitted to an ICU can incur severe emotional distress.[9] A recent review places the incidence of PTSD in parents of children in the PICU between 10% and 21%, with symptoms of PTSD occurring in up to 84% of families.[10] PTSD can occur no matter how routine the caregivers may view the process. The ICU is a unique and often terrifying experience for families and children. The process of ICU care involves multiple caregivers, changing shifts, and endless physicians. For families in the ICU, there can be a loss of control, significant financial worries, and other factors that affect coping. Helping parents cope with their child's critical illness and these stressors is a central part of intensive care. Parents may display behaviors that out of context may seem abnormal, such as excessive clinginess, intellectualizing the process, blaming others (including their spouses), minimizing, and seeking opinions everywhere (the internet, environmental care, etc.). We must attempt to understand what drives these behaviors to provide optimal care. We must help the parents be parents and educate them about their child's illness. This emphasizes that social workers, psychologists, and child and family therapists are all part of the critical care team.

With the move to family-centered care, we must address the issue of parental presence during invasive procedures and cardiopulmonary resuscitation (CPR) efforts. There is increasing literature that families would like to have the choice to stay during CPR events or invasive procedures and the parents do find benefit to being present.[11-14] We believe that allowing parents to stay during procedures or resuscitation is helpful for the parents coping with the trauma of a critically ill child. As each PICU addresses this issue there are several things to consider. Caregiver attitudes toward parental presence will need to be addressed, as the likelihood of this event increases over time. The decision to allow parental presence cannot be forced on providers. However, we have seen that resistance to family presence among providers is decreasing over time. A means for declining on the part of the clinician as well as the parent must be available. There must be someone identified who will stay with the family and support them. In our ICUs, this role been filled by social workers or members of the clergy. For those who are looking for assistance in making the transition to parental presence during CPR, there have been guidelines published from a national consensus conference.[15] Parental presence during invasive procedures may pose a different challenge as these events occur more frequently compared with CPR. In the same manner, someone other than the person performing the procedure should be looking after the family, even for what we believe to be routine procedures. We also must give younger trainees the opportunity to opt out of family presence during procedures.

A final topic that needs to be addressed is the use of palliative care services for our critically ill patients. There is a role for early consultation of palliative care, as we do not believe in restricting its use or support to just those patients who are near to death. We feel that there is a significant benefit to early engagement for children who are at high risk for mortality during their hospitalization, for children with complex diseases, or those where they cognitive and physical abilities following ICU discharge will be significantly different than previously. There are great benefits to palliative care intervention to provide families ongoing support and opportunities to develop coping mechanisms. Many different PICUs have developed automatic triggers for palliative care consultation, so as not to miss opportunities to improve family support. Examples of triggers can be PICU duration, episodes of CPR, prolonged mechanical ventilation, and specific types of surgeries. A review by the IPAL-ICU (Improving Palliative Care in the ICU) Advisory Board in 2014[16] addresses the needs and goals of palliative care integration in the PICU.[1]

Disclosure of Medical Errors

We believe it is ethically correct to disclosure medical errors to families. However, some clinicians may continue to resist due to concerns regarding litigation. In a survey of 1018 Illinois residents, 27% indicated they would sue, but 38% stated they would recommend the hospital if appropriate disclosure and remediation occurred.[17] The conclusion drawn by the author of the study was that "[p]atients who are confident in their providers' commitment to disclose medical errors are not more litigious and far more forgiving than patients who have no faith in their providers' commitment to disclose." Explanations of medical errors should come from the senior member of the team to the family. This is usually the current ICU attending, but can be the medical director of the ICU, based on the complexity of the incident and outcome. The discussion should include an explanation of what happened in layman's terms, how it occurred, the repercussions and change of care planned for the child, and what will be done to prevent a similar error in the future. We find it helpful to have the ICU social worker present to help validate concerns and provide support. The attending remains present until all questions are answered or additional time is scheduled if necessary. Most hospitals will track errors or negative outcomes through a quality assurance program. Depending on the incident, a "root cause analysis" should be performed. Medical errors will occur, but they should also be an opportunity to improve practice quality and prevent future events.

In an ICU setting, there unfortunately will also be a need to cope with death and dying.[18] Palliative care plays an important role when nothing medically can be done for the child. We also find their services exceedingly helpful for children with chronic medical conditions who are anticipated to die during a future admission. With a team approach, we try to minimize pain and suffering for the child and family at the end of life. Caregivers in and ICU must understand when to allow the families choices and support them over what may be their own beliefs and practices—as long as the goal remains to prevent further pain and suffering.[19] The awareness of medical futility is increasing over time. However, with this concept there is a significant interplay with financial, societal, ethical, personal, and religious opinions and feelings. It may be difficult to define futility, but when the pain and suffering of continuing life are more severe than the inevitability of death, care may become futile. However, pain relief and caring support for the child and family can never be classified as futile care.

Organization of the Pediatric Intensive Care Unit

Medical and nursing directors, hospital administrators, and representatives from pediatric medicine, anesthesia, surgery, and the pediatric subspecialties should be responsible for policy and procedures pertaining to the PICU and should make recommendations regarding personnel staffing, equipment purchases, and structural and design changes within the unit. The medical director oversees the quality of patient care, patient triage, implementation of policy and procedures, in-service education, and coordination of consultants. Physician coverage should be full-time geographic at the resident, fellow, and attending staff level, and should include in-house, full-time coverage at night. The nursing director should have special skills in pediatric intensive care, education, and personnel management. The nursing staff must be trained in all aspects of pediatric critical care and resuscitation. Staffing should be flexible enough to provide one-on-one patient care when necessary. A multidisciplinary in-service program is essential for continuing education and orientation. Other team members include respiratory therapists, physical therapists, nutritionists, social workers, laboratory technologists, pharmacists, and psychiatrists and psychologists for the patients and staff. All medical and support personnel should be encouraged to participate in rounds, educational endeavors, and team meetings whenever possible. There must be adequate workspace around each bed and enough storage space to keep life support equipment within reach. Space for reading, meeting, sleeping, and showering should be available for the staff. Space should be provided for parents to remain with their children during the day and for parents to sleep overnight. Parents should be encouraged to participate as much as possible in the care of their child. Each bed space should be standardized so that it can be used to provide any level of care. Private rooms are ideal, but if shared rooms are necessary, the distance between beds must be adequate to ensure privacy and minimize nosocomial infection. Isolation rooms should be available within the confines of the unit. Devices for diversion and entertainment should be available for conscious children. Television and computer games are often better than heavy sedation.[20,21] Adequate nurses and nursing involvement at the bedside will prevent potentially life-threatening events. Because sick children require close personal observation, centrally monitored nursing stations have little place in the PICU.

Cardiovascular System

STRUCTURAL AND FUNCTIONAL DEVELOPMENT

The shape of the heart is complete by 6 weeks' gestation, but myofibrillar density and maturation increase through the first year of postnatal life. During this time, myocytes engage in rapid protein synthesis and rapid cell growth, which requires a high intracellular concentration of nuclei, mitochondria, and endoplasmic reticulum. The greater number of nonelastic and noncontractile elements makes the neonatal myocardium less compliant, and it contracts less efficiently than the adult myocardium. In the fetus and newborn, the decreased ventricular compliance causes small changes in end-diastolic volume to induce large changes in end-diastolic pressure. In addition, augmentation of stroke volume by the Frank-Starling mechanism is less effective in young children. The newborn is more dependent on heart rate (HR) for maintenance of cardiac output.[22,23] Cardiac output increases only about 15% with volume loading; it increases much more by increasing the HR.[24] This is an important consideration when taking care of the critically ill infant.

DEVELOPMENT OF THE CIRCULATION

The adult and fetal circulation differs in many ways. The fetal circulation is distinguished by (1) the placenta as the organ of respiration, (2) high pulmonary vascular resistance (PVR), (3) low systemic vascular resistance (SVR), and (4) fetal ventricles that pump in parallel with right ventricular dominance. While the fetus lives in a low oxygen environment, the oxygen content of the blood of the fetus is similar to that of adults (20 mL of oxygen/100 mL of blood) because of a higher concentration of hemoglobin that has high affinity for oxygen. The neonatal circulation has several shunts—the ductus arteriosus, ductus venosus, and foramen ovale—that direct more oxygenated blood to the brain and heart and bypass the lungs. Changes then occur that allow the parallel circulation of the fetus to convert to the series circulation of the adult:

1. With the first breath, expansion of the lung, increased alveolar oxygen, an increase in pH, and neurohumoral

mediators and nitric oxide (NO) relax the pulmonary vasoconstriction.[25]

2. When the placenta separates from the uterine wall, the placental blood vessels constrict, and SVR and left ventricular afterload increase. The decrease in PVR plus increase in SVR raises left atrial pressure above right atrial pressure (RAP) and functionally closes the "flap valve" of the foramen ovale. The foramen ovale may not close anatomically for months to years, if ever. It is patent in at least 15% of adults.[26,27]
3. The decrease in PVR causes flow through the ductus arteriosus to reverse. This exposes the ductus to oxygenated systemic arterial blood, which along with the rapid decrease in prostaglandin E_2 after birth closes the ductus. Anatomic closure of the ductus requires several weeks.
4. The ductus venosus closes passively with removal of the placental circulation and readjustment of portal pressure relative to inferior vena cava pressure.
5. There is a further gradual decline in PVR secondary to structural remodeling of the muscular layer of the pulmonary blood vessels. During fetal life, the central pulmonary vascular bed has a relatively thick muscle layer. After birth, the muscle coat thins and extends to the periphery of the lung—a process that takes months to years to complete.

DEVELOPMENT OF AUTONOMIC CONTROL OF THE CIRCULATION

The functional integrity of autonomic circulatory control during fetal and perinatal development is still a matter of considerable speculation. The fetal heart has reduced catecholamine stores and increased sensitivity to exogenously administered norepinephrine (NE).

Adrenergic innervation of the human myocardium is complete between 18 and 28 weeks' gestation. Human newborns have low cardiac stores of NE and decreased numbers of sympathetic nerves after birth. Adrenergic responses are apparently present but diminished in newborn humans. In human neonates, the cholinergic system is completely developed at birth, and the heart is sensitive to vagal stimulation. Bradycardia is the probable response to an increase in autonomic tone. The baroreceptor reflex is present but incompletely developed at term in humans. In preterm infants, postural changes elicit no change in HR, suggesting an incomplete or attenuated baroreceptor response.[26] The chemoreceptor response is well developed in utero. The fetal bradycardia that occurs in response to hypoxia is thought to be mediated through chemoreceptors and may be similar to the oxygen-conserving mechanisms of diving animals.[27]

MYOCARDIAL METABOLISM

Fetal myocardial metabolism differs from that of adults. Relative "hypoxia" is normal in utero, and infant hearts tolerate hypoxia better than the hearts of adults do. This difference may be due in part to high concentrations of glycogen in fetal myocardial tissue and to the ability to more effectively use anaerobic metabolism. Because of the high glycogen stores and the ability to use anaerobic metabolism efficiently, the fetal/newborn heart is relatively resistant to hypoxia and can be resuscitated more easily if oxygenation and perfusion are reestablished reasonably quickly.

Oxygen consumption increases precipitously after birth, presumably because neonates are required to maintain their own temperature. A full-term infant's oxygen consumption in a neutral thermal environment is approximately 6 mL/kg/min; it increases to 7 and 8 mL/kg/min at 10 days and 4 weeks, respectively.

Common Cardiovascular Disease States

CONGENITAL HEART DISEASE

Congenital heart disease causes significant alterations in oxygenation, perfusion, and myocardial function after birth (Box 79.1). These abnormalities can be divided into hypoxic and normoxic lesions. The latter include obstructive lesions of the left side of the heart (mitral valve stenosis, aortic valve stenosis, aortic stenosis, anomalous pulmonary venous return, ventricular septal defect, or patient ductus arteriosus with a right-to-left shunt), whereas hypoxic lesions include tricuspid valve stenosis, pulmonary valve stenosis, pulmonary artery stenosis or aplasia, and the tetralogy of Fallot. Right-sided lesions cause hypoxia if the left-to-right shunting of blood is sufficient to cause congestive heart failure (CHF) and pulmonary edema. Newborns with significant congenital heart disease commonly have either cyanosis or CHF. The degree of dysfunction usually changes during the first few months of life as PVR decreases to adult levels. As PVR decreases, left-to-right shunting of blood usually increases, and the symptoms of CHF become more apparent. Many neonates with a significant ventricular septal defect, which may or may not be observed during the preoperative workup, have no left-to-right shunting for several weeks after birth; however, induction of alkalosis during surgery can increase shunting. In the newborn, the usual signs and symptoms of CHF include poor feeding, irritability, sweating, tachycardia, tachypnea, decreased peripheral pulses, poor cutaneous perfusion, and hepatomegaly. Many patients with pulmonary edema exhibit tachypnea without retractions. Cyanosis occurs with structural cardiac disease,

BOX 79.1 **Common Congenital Heart Malformations in the Newborn**

1. Cyanotic congenital heart lesions
   - Tetralogy of Fallot
   - Transposition of the great arteries
   - Hypoplastic left heart syndrome
   - Pulmonary atresia with an intact ventricular septum
   - Single ventricle
   - Total anomalous pulmonary venous return
   - Tricuspid atresia
2. Congenital heart lesions manifested as congestive heart failure
   - Ventricular septal defect
   - Patent ductus arteriosus
   - Critical aortic stenosis
   - Coarctation of the aorta

but other causes such as respiratory disease, increased PVR (persistent pulmonary hypertension), and methemoglobinemia must also be considered. Congenital heart disease is diagnosed by physical examination, electrocardiogram (ECG), chest radiograph, and echocardiogram, postnatally and via fetal echocardiography. Cardiac catheterization is occasionally performed as interventional therapy or as a diagnostic tool. Magnetic resonance imaging (MRI) is used to define the anatomy of congenital heart lesions before cardiac surgery. Initial treatment of congenital heart disease is aimed at relieving CHF, improving systemic perfusion, and improving or maintaining pulmonary blood flow. The ductus arteriosus must be maintained open in instances of hypoplastic left heart syndrome, aortic stenosis or atresia, interrupted aortic arch, and symptomatic neonatal coarctation of the aorta. In many cases, infusion of PGE_1 sustains life until definitive surgical correction can be performed.[28]

ACUTE CIRCULATORY FAILURE IN CHILDREN (SHOCK AND SEPSIS)

Shock

Shock is the inability to provide adequate oxygen to the tissues that require it. The condition of shock depends on the balance of supply and demand of oxygen. Typically the body delivers excess oxygen to the tissues. Under periods of stress or illness there can be a decrease in supply caused by diminished blood flow or as decreased oxygen in blood. There can also be increased demand or oxygen extraction from the tissues. The content of oxygen is the blood is dependent on the amount bound to hemoglobin and the amount dissolved in plasma. Oxygen content (CaO_2) (mL/dL) = (1.34g/dL) (SaO_2) (Hb) + (PaO_2) (0.003). The normal oxygen content is approximately 20 mL/dL. Delivery of oxygen to the tissues depends on oxygen content and cardiac output. Oxygen delivery ($\dot{D}O_2$) (mL/min) = oxygen content (CaO_2) × cardiac output (CO) × 0.01. Oxygen consumption ($\dot{V}O_2$) is the demand portion of the equation. Oxygen consumption ($\dot{V}O_2$) is independent of oxygen delivery ($\dot{V}O_2$) above a critical threshold and over a wide range. Below this critical threshold $\dot{V}O_2$ is dependent on $\dot{D}O_2$. For infants and young children, $\dot{V}O_2$ is estimated at 175 mL/min/m^2. Oxygen consumption is equal to oxygen delivery multiplied by oxygen extraction (O_2EX) by the body: $\dot{V}O_2 = \dot{D}O_2 \times O_2EX$. Oxygen extraction O_2EX is equal to $(CaO_2 - CvO_2)/CaO_2$. CaO_2 is the oxygen content of arterial blood and CvO_2 the oxygen content of venous blood. The difference between oxygen content of arterial and venous blood is predictably 4 to 6 mL/100 mL blood. Initially, as oxygen delivery decreases, the oxygen consumption can remain constant via increased extraction. Below a critical threshold in oxygen delivery, oxygen consumption becomes dependent on delivery. When oxygen to meet metabolic needs of the body cannot be met, nonessential metabolism is decreased or eliminated. Such metabolism includes growth, neurotransmitter synthesis, thermoregulation, and so forth. In this way the remaining oxygen can continue to be substrate for mitochondria. There are organs in the body, such as the kidney, skin, intestines, and skeletal muscle, that receive a high supply of blood relative to their metabolic needs. These organs also have a high proportion of sympathetic nerve innervations that allow for redistribution of blood flow to organs that with limited oxygen reserves such as the brain and heart.

Classification of Shock

There are several schemas which clinicians use to classify shock. Further within these classification schemas, disease states can fall into more than one category. One classification schema separates shock into the categories of hypovolemic, cardiogenic, distributive or vasogenic, and extracardiac obstructive.

Hypovolemic shock can be due to hemorrhage from trauma or gastrointestinal (GI) losses from internal bleeding. Nonhemorrhagic hypovolemic shock can be due to external losses of fluid from vomiting, diarrhea, polyuria, and poor fluid intake. Fluid redistribution in cases of burns, trauma, and anaphylaxis can also be a cause.

Cardiogenic shock may be myopathic due to decreased heart function. For adults this may commonly follow myocardial infarction. For children, myocarditis or cardiomyopathy are more common. Other causes of cardiogenic shock include mechanical failure such as valvular regurgitation or obstruction. Significant arrhythmias may result in cardiogenic shock when contractions are so asynchronous they decrease cardiac output.

Extracardiac obstructive shock results from a physical obstruction that prevents adequate forward circulatory flow. Causes include inadequate preload secondary to mediastinal masses, increased intrathoracic pressure from tension pneumothorax, constrictive pericarditis, and cardiac tamponade from pericardial effusions. Pulmonary hypertension, pulmonary embolus, and aortic dissection can cause obstruction to systolic contraction.

Distributive shock is caused by a decrease in SVR and the maldistribution of end-organ blood flow. Cardiac output may be increased in distributive shock, however, blood pressure may remain low due to a very low SVR. Septic causes of distributive shock can be related to bacterial, fungal, viral or rickettsial infections or toxins produced from these infections. Toxic shock syndrome would be an example of toxin-mediated hypotension. Anaphylactic or anaphylactoid reactions are a type of distributive shock. Systemic inflammatory response syndrome (SIRS) may present with distributive shock. Spinal shock can result in distributive shock on a neurogenic basis. Adrenal insufficiency with low circulating hormones results in distributive shock decreased SVR.

Diagnosis of Shock

Maintaining a high index of suspicion is important to rapidly identify shock in pediatric patients. Volume losses may be readily apparent from the history of present illness. Fever, rash and irritability may point to infection. However, cardiogenic shock may present with vague reports of decreased activity and level of alertness. In addition, if the patient's shock is currently compensated, changes in physical findings may be limited. A child in shock may present initially with tachycardia, cold extremities, and poor capillary refill. Further, in distributive shock, the child may be warm with just an isolated tachycardia. A brief pertinent physical exam should evaluate level of alertness, peripheral perfusion, mucous membranes, pulse rate and quality, respiratory effort, urine output, and blood pressure. In children, blood pressure may be preserved until the degree of shock has progressed. Hypotension is a sign of late and decompensated shock in children. Metabolic acidosis may not be present on the initial laboratory tests.

Compensatory Mechanisms

The body applies compensatory mechanisms with the onset of shock to maintain adequate tissue perfusion for as long as possible. There is redistribution of fluid from the intracellular and interstitium to the vascular space. There is a decrease in glomerular filtration to limit renal fluid losses. Renal fluid losses are also limited by the release of aldosterone and vasopressin. There is an increase in sympathetic activity and release of epinephrine. This results in decreased venous capacitance and some preservation of blood pressure. HR is increased as the body tries to maintain cardiac output. There is an increase in cardiac contractility through circulating catecholamines and adrenal stimulation. Increase in sympathetic nerve stimulation shunts blood away from nonvital organs. At the tissue level, transfer of oxygen from hemoglobin is increased by increased red blood cell (RBC) 2, 3-diphosphoglycerate, fever, and tissue acidosis.

Therapy and Outcomes

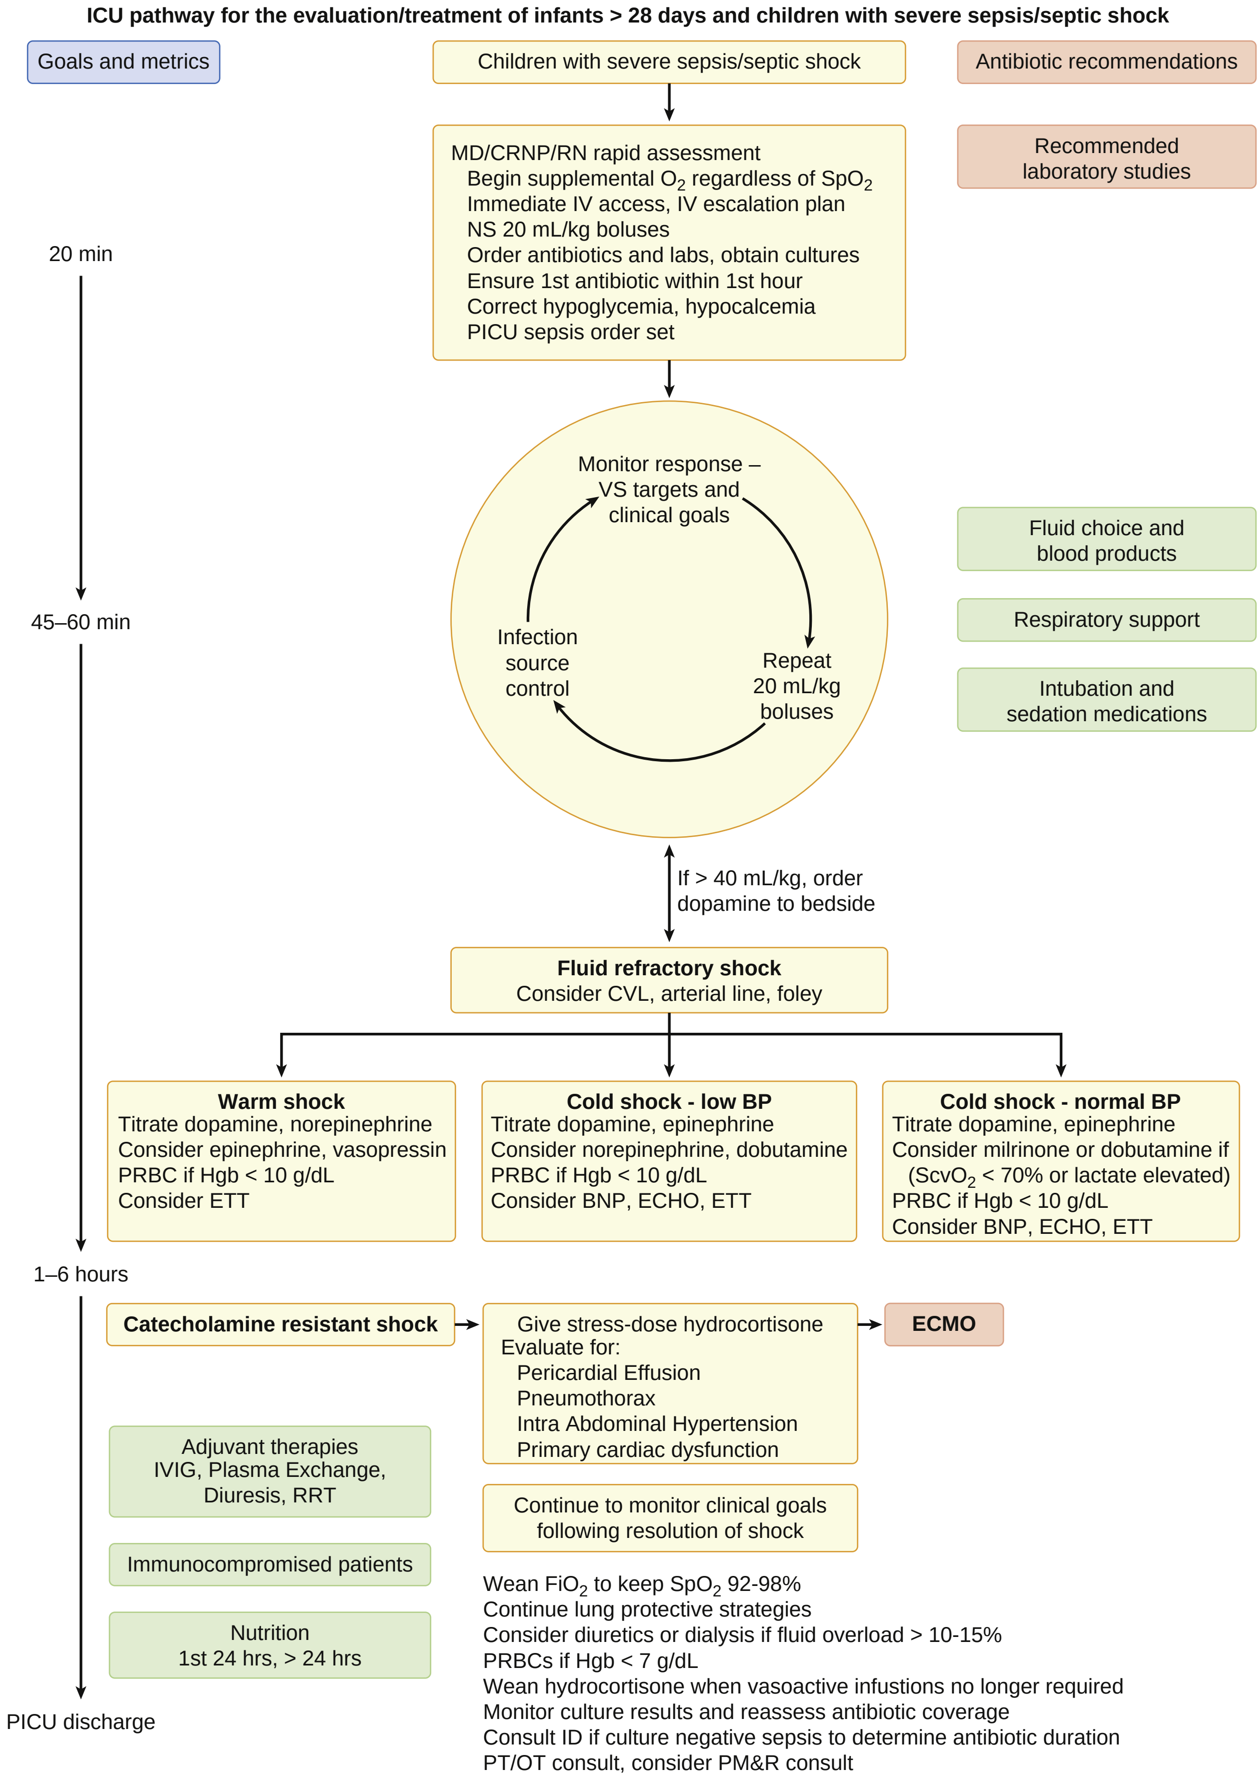
Aggressive therapy to treat pediatric septic shock appears to have resulted in improved outcomes. Therefore therapy for septic shock appears to be a good model for the treatment of shock in general. The overall goal of therapy in shock is to treat the underlying cause, return adequate oxygen delivery to the tissues, and remove metabolic products that developed during anaerobic metabolism. It appears the faster the body returns to adequate perfusion, the better the overall outcome. Many hospitals have developed sepsis pathways based on the data presented as follows that act as guidelines for resuscitation and are readily available to all care providers (Fig. 79.1).

In 1991 Carcillo et al.[29] described a population of 34 children that presented with septic shock to an emergency department. Shock was diagnosed based on hypotension for age, with decreased perfusion, poor peripheral pulses, cool extremities, and tachycardia. Sepsis was defined as a positive blood or tissue culture. Remarkably, within 6 hours of presentation, all the patients had a pulmonary artery catheter placed. The overall mortality for the group was 47%. However, in the nine patients who received more than 40 mL/kg of fluids in the first hour, there was only one death (mortality 11%). The authors point out this patient died with a second episode of sepsis 2 weeks later. In this study, the rapid fluid administration was not associated with an increase in cardiogenic pulmonary edema or ARDS.

In 2001 Rivers et al.[30] published a study in adult patients with septic shock showing early, aggressive, goal directed therapy in the first 6 hours of care improved mortality. There were 263 adults were enrolled; 133 received standard therapy based on clinician discretion. The 130 patients randomized to early goal-directed therapy followed protocols treating hypovolemia and supporting blood pressure with vasoactive agents if necessary. The baseline characteristics of the two groups were similar. The in-hospital mortality was 46.5% in the standard therapy group and 30.5% in early goal-directed therapy group ($P < .01$). Although in adults, this demonstrated the need for early aggressive intervention.

Following the Rivers publication, a task force was formed by members of the Society of Critical Care Medicine to address shock in children. Their work was published in 2002 as "Clinical Practice Parameters for Hemodynamic Support of Pediatric and Neonatal Patients in Septic Shock."[31] Their guidelines were incorporated into the American Heart Association's (AHA) Pediatric Advanced Life Support (PALS) Provider Manual. Their guidelines were translated into Spanish and Portuguese and disseminated widely. The effectiveness of these interventions as well as an 2007 update was published by the same group in 2009.[32] They highlighted significant improvements in mortality in dengue shock syndrome, malaria, and septic shock treated by community physicians using early goal directed therapy.[33-35] The guidelines include rapid recognition of shock and early antibiotic administration and early administration of intravenous (IV) crystalloid. The initial resuscitation should include 20 mL/kg of isotonic saline or colloid pushed as a bolus to over 60 mL/kg until there is an improvement in the patient's perfusion or rales or hepatomegaly develops. The goal is for the initial fluid resuscitation to occur in the first 15 minutes of therapy, and therapy should be initiated even if peripheral IV cannulation attempts fail, by placing and intraosseous (IO) device (Fig. 79.2). The guidelines target therapeutic end points of normal pulses with no difference between peripheral and central; capillary refill ≤ 2 seconds; warm extremities, normalization of blood pressure for age, mental status, glucose concentration, ionized calcium concentration; and urine output greater than 1 mL/kg/h. If central venous access is not readily obtained, consideration should be given for placement of an IO line. Cold shock (cold mottled extremities with prolonged capillary refill) should be treated with dopamine up to 10 μg/kg/min and then epinephrine 0.05 to 0.3 μg/kg/min if there is no improvement. Warm shock (brisk capillary refill) should be treated with NE. Arrangements should be made early to admit the child to an ICU. If shock is not reversed with the inotropic support, hydrocortisone should be considered for catecholamine resistant shock. Recommendations for stabilization in the ICU following the first hour of therapy include monitoring central venous pressure, central venous saturation, and cardiac output. Persistent shock that is resistant to catecholamines should prompt the clinician to rule out pericardial tamponade, pneumothorax, or significantly elevated intra-abdominal pressure that may be compromising circulation. In the absence of a correctible condition, extracorporeal membrane oxygenation (ECMO) should be considered.

There were several new recommendations in the 2007 guidelines that addressed changes in the literature between 2002 and 2007. It was identified that the availability of skilled practitioners to place central venous access could delay the initiation of inotropic support. Therefore, the 2007 guidelines recommended the use of a peripheral IV dopamine or epinephrine if there was delay in obtaining central venous access. Ongoing monitoring of the access site should be performed. It was not recommended to use NE in a peripheral IV, due to risk of extravasation. In the 2002–2007 interval there were several pediatric and adult studies indicating adrenal suppression and increased severity of illness adjusted mortality with the use of etomidate.[36,37] The 2007 guidelines do not



ICU pathway for the evaluation/treatment of infants > 28 days and children with severe sepsis/septic shock
Goals and metrics
Children with severe sepsis/septic shock
Antibiotic recommendations
MD/CRNP/RN rapid assessment
Begin supplemental O2 regardless of SpO2
Immediate IV access, IV escalation plan
NS 20 mL/kg boluses
Order antibiotics and labs, obtain cultures
Ensure 1st antibiotic within 1st hour
Correct hypoglycemia, hypocalcemia
PICU sepsis order set
Recommended laboratory studies
20 min
Monitor response – VS targets and clinical goals
Repeat 20 mL/kg boluses
Infection source control
Fluid choice and blood products
Respiratory support
Intubation and sedation medications
45–60 min
If > 40 mL/kg, order dopamine to bedside
Fluid refractory shock
Consider CVL, arterial line, foley
Warm shock
Titrate dopamine, norepinephrine
Consider epinephrine, vasopressin
PRBC if Hgb < 10 g/dL
Consider ETT
Cold shock - low BP
Titrate dopamine, epinephrine
Consider norepinephrine, dobutamine
PRBC if Hgb < 10 g/dL
Consider BNP, ECHO, ETT
Cold shock - normal BP
Titrate dopamine, epinephrine
Consider milrinone or dobutamine if (ScvO2 < 70% or lactate elevated)
PRBC if Hgb < 10 g/dL
Consider BNP, ECHO, ETT
1–6 hours
Catecholamine resistant shock
Give stress-dose hydrocortisone
Evaluate for:
Pericardial Effusion
Pneumothorax
Intra Abdominal Hypertension
Primary cardiac dysfunction
ECMO
Adjuvant therapies IVIG, Plasma Exchange, Diuresis, RRT
Immunocompromised patients
Nutrition 1st 24 hrs, > 24 hrs
Continue to monitor clinical goals following resolution of shock
Wean FiO2 to keep SpO2 92-98%
Continue lung protective strategies
Consider diuretics or dialysis if fluid overload > 10-15%
PRBCs if Hgb < 7 g/dL
Wean hydrocortisone when vasoactive infustions no longer required
Monitor culture results and reassess antibiotic coverage
Consult ID if culture negative sepsis to determine antibiotic duration
PT/OT consult, consider PM&R consult
PICU discharge

recommend the use of etomidate unless it is in the format of a randomized controlled trial. Ketamine with atropine was recommended for sedation for invasive procedures in infants and children. However, due to limited experience, ketamine could not be recommended for the newborn population.

The 2007 guidelines[32] recommend titrating therapy to cardiac output and indicate that there are several methods by which cardiac output can be measured. The use of pulmonary arterial catheters has decreased in pediatrics over time, but other methods are available. A good review of monitoring techniques was published by Mtaweh et al. in 2013.[38] Cardiac output can be monitored by newer techniques analyzing the arterial pulse wave, transpulmonary thermodilution, carbon dioxide rebreathing, echocardiography, bio-impedance of the thorax, and ultrasound continuous-wave Doppler. These techniques are less invasive than pulmonary artery catheters. However, many still require validation studies in pediatric, and they may not be available at all centers.

One additional area to be addressed in the 2007 guidelines is in the area of fluid removal.[32] A study published by Goldstein et al. in 2005 in pediatric patients with multiorgan failure, including acute renal failure requiring continuous renal replacement therapy (CRRT), showed improved survival in the group that had a lower percentage of fluid overload at the initiation of CRRT.[39] While supporting the primary premise of fluid resuscitation, the 2007 guidelines offered new recommendation for fluid removal in patients with fluid overload and multiorgan failure.[31] They recommended the use of diuretics, peritoneal dialysis, or CRRT in patients who had been adequately fluid resuscitated but were not able to maintain an even fluid balance through native urine output. Again, it should be noted that peritoneal dialysis and CRRT for pediatric patients may not be available at all centers. However, the association between fluid overload and mortality with acute renal failure has been seen in other studies and will likely be an ongoing issue in pediatric ICU care.

The concern for possible adrenal insufficiency during septic shock needs to be addressed by the clinician caring for the patient. There are certain instances where limited function of the adrenal axis is anticipated. This would include patients who have recently received glucocorticosteroids, ketoconazole, or etomidate. Further, patients with disease states such as purpura fulminans or those affecting the hypothalamus, pituitary, or adrenal glands will be at increased risk. Patients with adrenal insufficiency need supplemental corticosteroids. However, for children with septic shock but without these factors, it is not clear whether the risk of relative adrenal insufficiency or treatment with systemic steroids alter outcome. Dr. Zimmerman[40] reviewed the adult and limited pediatric literature in 2007 for therapeutic steroid use in sepsis. He highlighted adult studies showing high dose short courses of steroids are associated with decreased survival. Further, data from the CORTICUS trial[41] indicated that low dose steroids as a physiologic replacement during periods of vasopressor resistant shock resolve shock more quickly but there was no change in mortality. In turn, the 2007 guidelines were unchanged from 2002. Hydrocortisone treatment was only recommended for patients with absolute adrenal insufficiency or adrenal-pituitary axis failure and catecholamine-resistant shock. Absolute adrenal insufficiency was defined as peak cortisol concentration of less than 18 μg/dL obtained after corticotropin stimulation.

Cardiovascular Pharmacology

Pharmacologic support of the circulation includes positive inotropic and chronotropic agents, vasoconstrictors and vasodilators (afterload reduction), and antiarrhythmics (see Chapters 14, 18, and 86). Most currently used drugs have not been adequately tested in children, so dosage recommendations and anticipated effects must be extrapolated from adult doses and clinical experience.

Positive inotropic drugs are used to augment the cardiac output of patients with circulatory failure. Most inotropic agents also affect the HR and vasomotor tone. Tachycardia in a child is usually well tolerated and is frequently beneficial.[42] In a neonate whose ventricles are relatively noncompliant and whose stroke volume is less variable, tachycardia is an important means of augmenting cardiac output. Because drugs that increase the HR or contractility also increase myocardial oxygen consumption, adequate arterial oxygenation and sufficient metabolic substrates are required when these drugs are administered. The cardiovascular response to sympathomimetic amines is attenuated in the presence of severe acidosis and possibly sepsis; higher infusion rates of these drugs are required and need readjustment as the acidosis improves. Commonly used inotropes are listed with brief comments regarding their use in pediatric intensive care are provided in the following paragraphs (Table 79.1).

EPINEPHRINE

Epinephrine is useful for the treatment of shock in the presence of myocardial dysfunction. Typical starting doses in children are 0.05 to 0.2 μg/kg/min; with escalating doses up to 1 to 2 μg/kg/min, there is profound vasoconstriction in the periphery and abdominal organs to shunt blood to the heart and brain.

TABLE 79.1 Vasoactive and Inotropic Medications

Drug	Effect	Dose (μg/kg/min)	Inotropy	Chronotropy	Vasodilation	Vasoconstriction
Epinephrine (Adrenalin)	α, β	0.05-2.0	++	++		++
Isoproterenol (Isuprel)	β_1, β_2	0.05-2.0	++	++	+	
Dopamine (Intropin)	δ	1-3			+Renal splanchnic	
	β > α	5-15	+	+		+ or –
	β, α	>15	+	+		+
Milrinone		Bolus: 50 μg/kg over 15-min period	+		+	
		Infusion: 0.375-0.75				
Norepinephrine	α >> β	0.05-1.0	Slight+	+		++
Nitroprusside		0.5-10			++	
					Arterial > venous	
Nitroglycerin		1-20			++	

Dopamine

Dopamine is the most commonly infused inotrope in pediatric patients. Dopamine is the metabolic precursor of both NE and epinephrine. Its effects are dose dependent, with dopaminergic activity at low doses (although these low-dose dopamine effects have not been demonstrated in critically ill children); β-adrenergic activity with intermediate doses 5 to 10 μg/kg/min exhibiting chronotropic and inotropic effects; and some α-adrenergic activity at higher doses, with 10 to 20 μg/kg/min exhibiting peripheral vasoconstriction. Young children require higher doses of dopamine than adults do to produce the same effect. In one study, an infusion of 15 μg/kg/min was required to increase cardiac output above control levels after cardiac surgery.[43] This may reflect the decreased releasable myocardial stores of NE in immature ventricles. Therefore, in the sick preterm infant there can be decreased dopamine clearance with a much greater vasopressor response than expected.

Vasopressin

Vasopressin is a pituitary peptide hormone with method of action on the kidney and vasculature. In the kidney, vasopressin controls water reabsorption in the renal tubules, and in the vasculature, it causes vasoconstriction by stimulating smooth muscle V1 receptors. Its clinical applications include GI hemorrhage, central diabetes insipidus (DI), and as a second- or third-line agent to treat hypotension.

Isoproterenol

Isoproterenol is a synthetic, potent, nonselective β-agonist with strong chronotropic effects with very low affinity to α-adrenergic receptors, and is usually well tolerated in children. However, high doses of isoproterenol can cause myocardial ischemia.[44] Isoproterenol also induces vasodilation that is responsive to acute volume administration. It is often used for increasing HR in complete heart block, in the immediate postoperative period after cardiac transplantation to improve cardiac output by increasing HR in the denervated donor heart, and as a potent pulmonary vasodilator during pulmonary hypertensive crisis via β2-adrenergic receptor activity.

Dobutamine

Dobutamine provides positive inotropy and afterload reduction, β and α receptors. Its function is primarily as a inotropic agent but with less vasopressor activity compared with dopamine. It is only used as a continuous infusion of 5 to 20 μg/kg/min, and in some studies may increase myocardial oxygen In children but not in adults it causes tachycardia.[45,46]

Norepinephrine

NE, a drug with strong α- and β-agonist effects, has had a resurgence of use in infants and children.[47] Children with nearly normal cardiac function and marked peripheral vasodilation have good responses to this drug. It is especially useful in instances of warm septic shock, anaphylaxis, liver failure, and sympathetic blockade with regional anesthesia. It will increase SVR, but also limits mesenteric blood flow, including hepatic perfusion.

Milrinone

Milrinone is a selective phosphodiesterase III inhibitor that increases cyclic adenosine monophosphate by inhibiting breakdown. Milrinone has both inotropic and vasodilator effects, without acting on α and β receptors. This drug has improved the outcome of children who have low cardiac output syndrome after cardiac surgery.[48] The loading dose of milrinone is 25 to 75 μg/kg administered over a period of 10 minutes; the maintenance infusion rate is 0.25 to 0.75 μg/kg/min. Loading doses are often avoided in the ICU setting because of resultant hypotension. Renal failure significantly increases the elimination half-life of this drug.[49,50] Outside the cardiac ICU, milrinone is used for vasoconstricted septic shock and may have a role in the treatment of pulmonary hypertension.

Levosimendan

Levosimendan is a novel agent that increases the sensitivity of the contractile apparatus to calcium increasing inotropy by binding to cardiac myocyte troponin C. This agent will increase cardiac ejection fraction, while reducing catecholamine dose with minimal effects on blood pressure and HR. In children, the most common indications have been for cardiac failure or post–cardiac surgery, with a loading does of 612 μg/kg followed by an infusion of 0.1 to 0.2 μg/kg/min.[51,52]

Nesiritide

Nesiritide is a recombinant form of the human B-type natriuretic peptide, the hormone release from the cardiac ventricles in response to volume overload and increasing mechanical wall stress. The action is on guanylate cyclase with resulting venous and arterial vasodilation. In addition, B-type natriuretic peptide leads to myocardial relaxation (lusitropy) and natriuresis. In children, it has been used to decrease central venous pressure and increase urinary output.[53] Usual dosing suggestions for children and adults: initial 2 μg/kg bolus followed by a continuous infusion of 0.005 to 0.01 μg/kg/min.

Digitalis

Digitalis is useful for the long-term treatment of myocardial failure in children but may not be effective in neonates.[54] Because of its long half-life and unpredictability, digitalis should be administered cautiously to children who have changing levels of serum potassium, calcium, and pH. In these cases, it is more appropriate to use rapid-acting, titratable inotropic agents.

Calcium

When serum ionized calcium levels are below normal, administration of calcium produces a positive inotropic effect. If the patient's ionized calcium levels are normal, less marked inotropic effects occur. Low ionized calcium levels most commonly occur in patients with DiGeorge's syndrome, when large volumes of citrate-containing blood products are rapid administered, and in neonates with relatively unstable calcium metabolism. Calcium also has effects on the cardiac conduction system. Rapid administration of calcium can cause severe bradycardia or asystole. This effect may be exaggerated in hypokalemic children or in those receiving digitalis. The vasomotor effects of calcium are controversial, but most reports show an increase in both SVR and PVR when the drug is administered.[55]

Bicarbonate Therapy

Severe acidosis decreases myocardial function and tissue perfusion. Correction of acidosis with 1 to 2 mEq/kg of sodium bicarbonate is indicated for a pH below 7.20 if ventilation is adequate (PCO_2 <40 mm Hg if possible). Treatment is necessary because the circulatory system is refractory to sympathomimetic amines when the pH is less than 7.00. After initial correction of pH, persistence or reappearance of metabolic acidosis suggest a continuing underperfused state and the need for further therapy. Administration of sodium bicarbonate is only a stopgap measure to improve the response to drugs. Repeat infusions of sodium bicarbonate can cause hypernatremia and hyperosmolarity. Every 50 mEq of bicarbonate administered produces 1250 mL of CO_2 when the bicarbonate is fully reacted with acid. Consequently, adequate ventilation must be ensured while the drug is administered to avoid worsening the acidosis. Trishydroxymethylaminomethane (THAM) is an alternative to sodium bicarbonate, but larger volumes of THAM are required to produce the same amount of acid-base correction, which may be a problem in patients who have CHF. THAM does not increase $PaCO_2$.

Vasodilators

Vasodilators are used to control systemic hypertension, increase cardiac output by decreasing afterload, control pulmonary hypertension, and control cardiac shunting. Vasodilators are an effective treatment of systemic hypertension and increase cardiac output in children with CHF. Treatment of pulmonary hypertension and intracardiac shunting with vasodilators has met with limited success because they decrease both PVR and SVR, which may increase extrapulmonary right-to-right shunting and further reduce pulmonary blood flow.

Nicardipine

Nicardipine is a dihydropyridine calcium channel-blocking agent used as an IV infusion that has powerful, antihypertensive effects in children. Studies have shown that the rapid onset of action is usually within 1 minute, adding to the profile appropriate for treating severe hypertension. Flynn et al. reports that nicardipine is an effective antihypertensive medication in children ranging in age from 2 to 18 years.[56] In our institution, nicardipine is the drug of choice for hypertensive crisis. Infusion ranges: 0.5 to 1.0 μg/kg/min up to 3.0 μg/kg/min.

Sodium Nitroprusside

Sodium nitroprusside relaxes arteriolar and venous smooth muscle, which decreases afterload and preload. The half-life of sodium nitroprusside is only minutes, making it safe to titrate the drug to a desired effect. Nitroprusside is commonly used to control severe systemic hypertension, to provide controlled hypotension to reduce blood loss, and to increase cardiac output in children with low cardiac output syndromes (myocarditis, post–cardiac surgery status).[57] Sodium nitroprusside can generally be used for days without problems, although cyanide and thiocyanate poisoning develops in some children, especially those with renal failure or reduced renal perfusion. Serum thiocyanate levels of 10 mg/dL are associated with weakness, hypoxia, nausea, muscle spasms, and disorientation. When these symptoms occur, nitroprusside administration should be discontinued immediately.

Hydralazine

Hydralazine is used to control systemic hypertension because it relaxes arterial smooth muscle more than it relaxes veins. Administration of the drug can cause headache, nausea, dizziness, sweating, and tremors. The most important acute side effect is tachycardia, which may increase cardiac output; labetalol, a β-antagonist, can counteract this effect.[58]

Tolazoline and Phentolamine

These competitive α-adrenergic blockers have had varied success in the treatment of pulmonary hypertension.[59] However, they are effective in treating the symptoms of pheochromocytoma preoperatively. Serious side effects of these drugs include tachycardia, ventricular arrhythmias, hypotension, and tissue edema.

Prostaglandin E_1

PGE_1 acts directly on vascular smooth muscle and has greatly improved the care of neonates with heart disease. At infusion rates of of 0.1 μg/kg/min, patency of the ductus arteriosus is maintained and a closed ductus reopens in some neonates. The drug is indispensable in the care of patients with ductus-dependent cardiac lesions, such as interrupted aortic arch, critical aortic stenosis, or hypoplastic left heart syndrome, where systemic blood flow is supplied through the ductus arteriosus. It is equally important for the care of patients who have pulmonary atresia or critical pulmonic stenosis.[28] Apnea, fever, and hypotension are common side effects of this drug.

Nitric Oxide

NO is an endothelium-derived relaxing factor that selectively vasodilates the pulmonary vasculature.[60] When administered by inhalation to patients with pulmonary hypertension, NO reduces PVR. It improves the survival of neonates who have reactive pulmonary hypertension.[61-63] This compound is inactivated by hemoglobin before it reaches the systemic circulation. On rare occasions, NO causes systemic vasodilation or clinically significant methemoglobinemia when administered at 5 to 80 ppm.[62]

Disorders of Cardiac Rhythm

Sinus tachycardia or an elevated HR for age is not considered an arrhythmia. However, patients with a significantly increased HR may be the most critically ill in the ICU. Causes of tachycardia include hypovolemia, fever, pain, anxiety, CHF, myocardial disease and dysfunction and thyrotoxicosis. With all of these causes, the goal is to treat the underlying disease state and not the tachycardia. For children without underlying heart disease, temporary increases in HR up to 180 to 200 beats/min is well tolerated. This is also not uncommon; children cannot increase their stroke volume so they increase their cardiac output by increasing their HR. Again, the goal is not to specifically control an elevated HR but to treat the cause of the tachycardia. Sinus arrhythmia is a phasic acceleration and slowing of the HR that occurs with respiration. This is not an uncommon finding. It indicates that the patient has a vagal tone greater than sympathetic tone and it can indicate that there is good cardiac reserve. A slow HR or sinus bradycardia is another relatively common heart rhythm seen in the ICU. It is an unremarkable finding in an older teenage patient who is relatively fit. Other potential causes can include increased intracranial pressure (ICP), hyperkalemia, hypothermia, profound hypoxia, and hypothyroidism. These causes should also be investigated. A slow HR is being seen more commonly with the increased of Dexmedetomidine but can also occur with beta blockers or Digoxin use. Sinus node dysfunction can occur following repair of congenital heart disease in children. Temporary slowing may be treated with the transcutaneous pacemaker placed during surgery. In the absence of myocardial pacing, if there is complete heart block or a very slow ventricular escape rate, a pacemaker may be needed shortly after the cardiac surgery. Otherwise, some amount of time is given to see if this will resolve.

Normal cardiac conduction starts in the sinus node. The electrical activity propagates through the internodal pathways in the atrium, is delayed in the AV node, it travels though the bundle of His, and then is conducted to the ventricles through the left and right bundle branches. Supraventricular tachycardia (SVT) is an elevated HR occurring at the level of the atrium, the AV node, or both. SVT typically has a narrow QRS morphology. Sinus tachycardia is therefore not a type of SVT but an acceleration of the normal conduction pathways. SVT includes reentrant and non-reentrant tachycardias.

The reentrant tachycardias include AV node reentrant tachycardia (AVNRT), orthodromic reciprocating tachycardia (ORT), and atrial flutter. AVNRT is what is classically thought of as pediatric SVT. The reentrant tachycardias occur due to the presence of an accessory conduction pathway that allows for abnormal electrical conduction in the heart. The presence of the abnormal pathway may be apparent on a standard ECG such as the case of Wolf-Parkinson-White (WPW). Alternatively the abnormal pathway may not appear on an ECG and is described as a concealed pathway. Concealed pathways are non-WPW ORT. In AVNRT, the AV node itself is the area in which the reentrance occurs. In atrial flutter there is a microreentrant circuit within the atrial tissue itself. In children, the circuit is typically near the tricuspid valve. In atrial flutter, after the reentrant circuit in the atria, the conduction proceeds through the AV node, where it is slowed. The reentrant circuit is small, and the rates of atrial flutter can be very high. As the conduction is slowed in the AV node, these high rates are not usually conducted to the ventricle. However, if atrial flutter or fibrillation occurs in a patient with WPW, the accessory pathway can allow conduction of the electrical impulse at a rate much greater than through the AV node. This can lead to ventricular tachycardia or fibrillation and can cause sudden death.

The non-reentrant causes of SVT occur due to abnormal automaticity of myocardial tissue. Causes of abnormal automaticity include atrial fibrillation and ectopic atrial tachycardia (EAT). In non-reentrant SVT, the elevated atrial rate is slowed as conduction goes through the AV node. In children, atrial fibrillation is caused by disorganized circuits typically near the pulmonary veins. This rhythm is described as irregularly irregular. EAT is rapid atrial beats that are consecutive and occur without sinus morphology. There can be one focus of the rapid atrial beats. Alternatively, in multifocal or chaotic atrial tachycardia, there can be several different atrial origins. Brief periods of EAT usually do not cause much sequel but can lead to cardiomyopathy if it is prolonged.

Treatment of reentrant SVT is based on whether the patient is clinically unstable or stable. The abnormal reentrant circuit can be interrupted with synchronized cardioversion or other methods. If the patient is unstable, reentrant SVT is treated with synchronized cardioversion with a dose of 0.5 to 1 J/kg. If the patient is stable, there is time to try other therapies. Therapies that increase vagal tone such as ice to the eyes or a Valsalva maneuver may interrupt the reentrant circuit. The medication adenosine will temporarily block conduction through the AV node. Adenosine can be used to interrupt episodes of reentrant SVT that have a reentrant circuit using the AV node. If the reentrant circuit does not include the AV node adenosine might not stop the tachycardia, but it may be helpful with diagnosis. Following administration of adenosine, there will be a period of sinus pause. Adenosine is metabolized by erythrocytes so it is a short acting medication. Equipment to perform cardioversion should be immediately available when adenosine is given. The initial dose is 0.1 mg/kg, and the dose should be given quickly with a sufficient flush. It is more effective when given centrally if available. If it is not effective at the dose of 0.1 mg/kg, the second dose can be increased to 0.2 mg/kg. Higher doses than this are not likely to be more effective, and if the SVT persists, other medications such as amiodarone, procainamide, or verapamil may be necessary. Amiodarone can block an accessory pathway as well as the AV node. If given too quickly, amiodarone will decrease the blood pressure. For both amiodarone and procainamide, continuous infusions may be necessary after the loading dose. Verapamil will block the AV node for a much longer period of time than adenosine. However, in younger patients (<2 years), verapamil may induce other life-threatening arrhythmias. If a patient has SVT, a cardiology consult should be obtained. This is because an echocardiogram may be beneficial, and depending on the cause, there may be a need for long-term follow-up.

Junctional ectopic tachycardia is caused by abnormal automaticity in an area around the atrioventricular junction. This is not a common pediatric arrhythmia but can occur following repair of congenital heart disease. The most common lesion with which this occurs is tetralogy of Fallot.

Wide complex tachycardias are assumed to arise from the ventricle until proven otherwise. SVT can cause a wide complex tachycardia if there is aberrancy of the conduction through the pathways in the ventricle. However, given the risk of delaying therapy, all wide complex tachycardias should initially be treated as ventricular tachycardia. If there is no pulse, initiate CPR, defibrillate, and follow PALS guidelines. If the patient has a pulse and stable blood pressure, there may be time to consider other therapies. These therapies are cardioversion or use of medications such as adenosine, amiodarone, or procainamide. Ventricular fibrillation is treated with CPR, defibrillation, and then medications following PALS guidelines. Ventricular rhythms should be quickly examined for the possibility of Torsades de Pointes, as giving magnesium will be especially helpful.

In the course of following the continuous rhythm strip of all children in the PICU, common abnormalities may be noted. A prolongation of the PR interval or first degree heart block can occur in otherwise normal children. Typically, these children are asymptomatic. Second-degree heart block occurs as Mobitz Type I and Mobitz Type II. Mobitz Type I is also known as *Wenckebach*. This is a gradual prolongation of the PR interval until a QRS is not seen and then the cycle restarts. This occurs due to delay of the electrical signal in the AV node, and it can be a benign phenomenon. Mobitz Type II is less likely to be a benign phenomenon. The PR interval remains constant, but intermittently there is no QRS or ventricular beat. This phenomenon is evidence of disease of the His-Purkinje fibers and can progress to complete heart block. Mobitz Type II occurs much less frequently in children as compared with adults. Complete heart block or third-degree AV block is the complete dissociation of atrial and ventricular activity. In complete heart block, the atria contract at a rate greater than the ventricle. Ventricular contraction occurs through ventricular escape. Congenital complete heart block can occur in infants born to mothers who have an autoimmune disorder such as lupus. When there is damage to the conduction pathway during surgery for congenital heart disease, complete heart block can occur. As immediate treatment of complete heart block, the ventricular rate may be increased with IV isoproterenol. When this is ineffective, transthoracic or transvenous pacing will be necessary until definitive therapy can be arranged.

Premature beats are also seen quite frequently in a PICU setting. Premature atrial contractions are usually benign and are caused by automaticity of atrial tissue other than the sinus node. Premature ventricular contractions (PVC) are usually benign with a few considerations. The presence of a central venous catheter touching the heart may cause increased PVCs, and if present, the catheter should be pulled back. Electrolyte abnormalities; typically of potassium, magnesium, and calcium, may cause PVCs. The frequency of PVCs may improve as the electrolytes are corrected. Exogenous catecholamines may cause PVCs, and the frequency of PVCs may improve if the catecholamines can be decreased. Endogenous catecholamines may cause PVCs, and the frequency may be decreased if pain or anxiety is treated.

HYPERTENSION

Essential hypertension is uncommon in children, but when it occurs, it is often associated with another disease process (Box 79.2) and is frequently difficult to control. The acute onset of severe systemic arterial hypertension is a medical emergency that has the potential of causing cardiovascular decompensation, encephalopathy, seizures, and intracranial hemorrhage. In older children, the neurologic manifestations of hypertension are more likely to precede cardiovascular decompensation. Neonates with severe hypertension are frequently initially found to have CHF. Treatment of hypertension is tailored to the disease process, the absolute degree of hypertension, and the presence of cardiovascular or neurologic symptoms.[64,65]

Neonatal Resuscitation

Profound changes occur in the cardiovascular and respiratory systems at birth. Failure to successfully make these changes may result in death or central nervous system (CNS) injury. Consequently, someone capable of performing neonatal resuscitation must be present at every delivery. Wasting time finding someone to resuscitate the neonate may be disastrous for the infant. This section discusses the causes and effects of cardiorespiratory insufficiency at birth and the techniques of resuscitation. When possible, the recommendations of the American Academy of Pediatrics have been followed.

BOX 79.2 Causes of Severe Hypertension in Children

Renal

Acute glomerulonephritis (e.g., poststreptococcal, Henoch-Schönlein purpura)
Hemolytic-uremic syndrome
Chronic glomerulonephritis (all types)
Acute and chronic pyelonephritis
Congenital malformations (dysplasia, hypoplasia, cystic diseases)
Tumors (e.g., Wilms, leukemic infiltrate)
Post–renal transplantation status; also rejection
Oliguric renal failure
Trauma
Obstructive uropathy
After genitourinary surgery
Blood transfusions in children with azotemia

Cardiovascular

Coarctation of the aorta
Renal artery abnormalities (e.g., stenosis, thrombosis)
Takayasu's disease

Endocrine

Pheochromocytoma
Neuroblastoma
Adrenogenital disease
Cushing syndrome
Hyperaldosteronism
Hyperthyroidism
Hyperparathyroidism

Iatrogenic

Intravascular volume overload
Sympathomimetic administration (e.g., epinephrine, ephedrine)
Corticosteroid administration
Rapid intravenous infusion of methyldopa

Miscellaneous

Immobilization (e.g., fractures, burns, Guillain-Barré syndrome)
Hypercalcemia (e.g., hypervitaminosis D, metastatic disease, sarcoidosis, some immobilized patients)
Hypernatremia
Stevens-Johnson syndrome
Increased intracranial pressure (any cause)
Dysautonomia
After resuscitation

Guidelines for neonatal resuscitation have been issued by many organizations, including the AHA and the American Academy of Pediatrics.[66]

INITIAL ASSESSMENT OF THE FETUS AT BIRTH

Initial stabilization should begin with a rapid evaluation of the newborn to determine if the infant is term, breathing, or crying, and has a normal tone (Table 79.2).[66]

ONGOING ASSESSMENT

Ongoing assessment consists of three signs: HR, respirations, and oxygenation. The preferred method for auscultation of HR is by auscultation. All of these vital signs should be determined within the first 30 seconds.

TABLE 79.2 Evaluation of the Newborn

Clinical Condition	Intervention
Initial resuscitation	Clear infant airway Warm, dry, stimulate, position Evaluate HR, respirations, color
HR > 100 beats/min, breathing, no cyanosis	Observation
HR > 100 beats/min, but persistent respiratory distress or cyanosis	Clear airway SpO_2 monitoring Consider CPAP
Apnea, gasping, or HR < 100 beats/min	Bag-mask PPV SpO_2 monitoring
After initiation of resuscitation (PPV), HR > 100 beats/min, effective ventilation	Post-resuscitation care
HR < 60 beats/min	Consider intubation Chest compressions Coordinate PPV
HR = 60-100 beats/min	Continue with PPV SpO_2 monitoring

CPAP, Continuous positive airway pressure; *HR,* heart rate; *PPV,* positive pressure ventilation; *SpO_2,* saturation of peripheral oxygen.

CLEARING THE AIRWAY

Proper positioning by placing the infant in the sniffing position is recommended, and the practitioner must try to avoid either underextension or hyperextension, both of which will obstruct the airway. Deep sucking should be avoided even in healthy, vigorous newborns, because of risks of vagal-mediated bradycardia.[67] This does not apply to newborns who may have airway obstruction or the depressed infant with meconium (covered later in this section.)

TEMPERATURE CONTROL

During the initial resuscitation period, the goal temperature for the newborn is normothermia. The initial step is to dry the infant and warm the infant to a goal axillary temperature of 36.5°C. The goal for each neonate is euthermia. Infants wrapped in polyethylene from the neck down will avoid evaporative heat loss. Controlled hypothermia should only be attempted in select tertiary centers within hours after birth in infants with hypoxic-ischemic encephalopathy (HIE).

OXYGEN

One of the recent changes in neonatal resuscitation in the 2011 Neonatal Resuscitation Program Guidelines is the recommendation of positive pressure ventilation (PPV) with room air, unless chest compressions or medications are needed during the resuscitation then the recommendation are still for PPV with 110% oxygen. It is important to place a preductal (right hand) oximeter probe on the newborn if PPV is initiated. For the preterm infant, oxygen should be blended to goal saturation targets. In summary: (1) Use room air in the baby is cyanotic or needs PPV. (2) If the baby is less than 32 weeks, titrate oxygen (Table 79.3).

TABLE 79.3 Preterm Infant (<32 Weeks): Titrate Oxygen Using Oxygen Blender to Achieve Target SpO_2

Time after Birth (min)	Target SpO_2 (%)
1	60-65
2	65-70
3	70-75
4	75-80
5	80-85
10	85-95

SpO_2, Saturation of peripheral oxygen.

(3) Use 100% oxygen if chest compressions or medications are given, then titrate to targeted SpO_2. (4) Apply oximeter to right hand (preductal).

VENTILATION

Breathing usually begins by 30 seconds after birth and is sustained by 90 seconds of age. A few minutes after birth, the respiratory rate (RR) of normal neonates is between 40 and 60 breaths/min. The absence of a pause between inspiration and expiration helps develop and maintain functional residual capacity (FRC). Apnea and bradypnea prolong exhalation, reduce FRC, and cause hypoxia. Causes of apnea and bradypnea include severe acidosis, asphyxia, maternal drugs, infections, and CNS damage. Tachypnea (>60 breaths/min) occurs with hypoxemia, hypovolemia, metabolic and respiratory acidosis, CNS hemorrhage, pulmonary gas leaks, pulmonary disease (e.g., hyaline membrane disease, aspiration syndromes, infections), pulmonary edema, and maternal drugs (e.g., narcotics, alcohol, magnesium, barbiturates).

Recommendations now are that initial breaths should be at 20 cm H_2O. Ventilation should be performed at 40 to 60 breaths/min with reassessment of HR, color, and breath sounds. In the neonate, rising HR may be the best assessment of adequate ventilation. If gastric distention becomes a problem, hindering compliance, a gastric tube may be placed (8 Fr) to improve compliance. Both sides of the chest should rise equally and simultaneously with inspiration, but the amount of rise should not exceed that associated with the neonate's normal spontaneous breathing. The presence of breath sounds may be misleading because they are well transmitted within the neonate's small chest. A difference in breath sounds between the two sides of the chest should raise suspicion of endobronchial intubation, pneumothorax, atelectasis, or a congenital anomaly of the lung. The presence of loud breath sounds over the stomach suggests esophageal intubation or a tracheoesophageal fistula. If ventilation is adequate, the neonate will become pink, initiate rhythmic breathing, and have a normal HR.

Because most asphyxiated neonates have no lung disease, they can be effectively ventilated with peak airway pressures lower than 25 cm H_2O, even for the first few breaths. Those with stiff lungs (e.g., erythroblastosis fetalis, congenital anomalies of the lung, pulmonary edema, severe meconium aspiration, diaphragmatic hernia) may require higher inspiratory pressure to ventilate their lungs and are more likely to have pulmonary gas leaks. To reduce this likelihood, the lungs should first be ventilated with an inspiratory pressure of 15 to 20 cm H_2O and inspiratory rate of 150 to 200 breaths/min. If low-pressure (low-volume), high-rate ventilation does not improve the oxygenation, higher pressure and volume may be required. Failure to adequately ventilate the lungs at birth may worsen hypoxemia and lead to CNS damage or even death. If P_aO_2 exceeds 70 to 80 mm Hg or SaO_2 exceeds 94%, the inspired oxygen concentration should be reduced (if increased concentrations of oxygen are used) until SaO_2 and PaO_2 are normal for age. Oxygenation is maintained at the low range of normal in neonates 34 weeks' or less gestation to avoid the retinopathy of prematurity.[68] The neonate's HR should be monitored continuously during endotracheal intubation because the process of tracheal intubation may cause arrhythmias in hypoxic neonates.

If the practitioner is having difficulty with bag mask ventilation or fails intubation, a laryngeal mask airway (LMA) should be considered.[69,70]

PNEUMOTHORAX

Pneumothorax occurs in 1% of all vaginal deliveries, in 10% of meconium-stained neonates, and in 2% to 3% of neonates who require mechanical ventilation in the delivery room. The hemithorax containing free air is usually hyperexpanded and moves poorly with ventilation. The point of maximum cardiac impulse is shifted toward the side without the pneumothorax. Heart tones may be muffled.

If a small, high-intensity cold light is placed directly on the skin of the neonate's chest, the involved side of the chest will glow if a pneumothorax is present.[71] Pneumothoraces are relieved by needle or chest tube drainage.

ENDOTRACHEAL INTUBATION

The head should be placed in a neutral or "sniffing" position during bag-and-mask ventilation and tracheal intubation. An appropriately sized endotracheal tube (ETT) is inserted and its tip is placed 1 to 2 cm below the vocal cords, depending on the size of the neonate. Usually, this means that the distance from the tip of the tube to the gums is 7, 8, 9, or 10 cm in 1-, 2-, 3-, and 4-kg infants. A small gas leak should be present between the ETT and trachea when the ventilation pressure is 15 to 25 cm H_2O. This usually entails the use of a 2.5-mm (internal diameter) tube for neonates weighing less than 1.5 kg, a 3.0-mm tube for those between 1.5 and 2.5 kg, and a 3.5-mm tube for those weighing more than 2.5 kg. Successful tracheal intubation is confirmed by observing the ETT pass through the vocal cords, by observing bilateral chest movement with each mechanical inspiration, and by observing condensation in the ETT during exhalation. Breath sounds should be much louder over the chest than over the abdomen, and the skin color, HR, and SaO_2 should improve with positive-pressure ventilation. Carbon dioxide should be present during exhalation. However, the small tidal volumes and low pulmonary blood flow of some infants at birth may make it difficult to use capnography effectively.

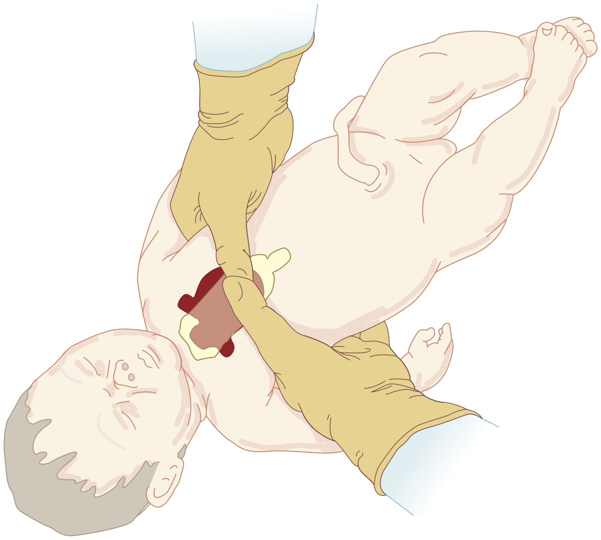

Fig. 79.3 Neonatal chest compression. For simplification, ventilation is not shown. (From Gregory GA. Resuscitation of the newborn. *Anesthesiology*. 1975;43:225.)

CARDIAC COMPRESSIONS

Place both thumbs on the sternum and allow the fingers to support the back (Fig. 79.3). Compress the sternum to approximately one-third the depth of the chest. Three compressions should be performed with a breath in place of the fourth compression for an effective compression rate of 90 compressions and 30 breaths/min. HR should be evaluated every 45 to 60 seconds, and if after adequate ventilation and compressions for 60 seconds the HR is still less than 60 beats/min, then medications should be considered.

MEDICATIONS

Resuscitation with medications are needed only for the infant that is critically depressed or presents with significant anomalies leading to cardiovascular depression. There should be a quick reference drug list designed for each delivery room for easy access for these rare occasions, and should help with dosing based on an estimated weight of the infant at birth. IV route of administration is the preferred for administration of resuscitation medications; however, IO and umbilical venous catheters can be placed rapidly by trained individuals and may be life-saving.

Epinephrine

The primary medication used in the resuscitation of a newborn is epinephrine, and should be given if the infant's HR is less than 60 bpm, 45 to 60 seconds after the initiation of PPV and chest compressions. The recommended dose is 0.1 to 0.3 mL/kg of 1:10,000 concentration; (0.01-0.03 mg/kg), followed by a 1 mL flush of saline. While IV administration is preferable, if venous access is not obtained, it is appropriate to give epinephrine via the ETT. In this instances the practitioner, should give a higher dose of Epinephrine: 0.5 to 1 mL/kg of 1:10,000 concentration; (0.05-0.1 mg/kg). Epinephrine can be repeated every five minutes, as needed, while re-evaluating HR every 45 to 60 seconds.

Naloxone

Naloxone (Narcan) is not recommended as an initial response to respiratory distress in neonatal resuscitation.[66,72] Neonates should be supported on PPV, even in women who have received narcotics less than four hours prior to delivery. However, if respiratory depression continues, naloxone can be considered. In addition, naloxone should be avoided in an infant whose mother has a history of narcotic dependence due to the risk of seizures from withdrawal.

DETECTION OF HYPOVOLEMIA

Hypovolemia is detected by measuring arterial blood pressure and by physical examination (i.e., skin color, perfusion, capillary refill time, pulse volume, and extremity temperature).

CVP measurements are useful in detecting hypovolemia and in determining the adequacy of fluid replacement. The venous pressure of normal neonates is 2 to 8 cm H_2O. If CVP is less than 2 cm H_2O, hypovolemia should be suspected.

TREATMENT OF HYPOVOLEMIA

Treatment of hypovolemia requires expansion of intravascular volume with blood and crystalloid. Albumin may also be used, but evidence of its effectiveness is limited. If it is suspected that the neonate will be hypovolemic at birth, Rh-negative type O packed RBCs should be available in the delivery room before the neonate is born.[73] Crystalloid and blood should be titrated in 10 mL/kg and given slowly over 10 minutes, if hemodynamics allow, to limit the risk of intraventricular hemorrhage.

Occasionally, enormous volumes of blood and fluid are required to raise arterial blood pressure to normal. At times, more than 50% of the blood volume (85 mL/kg in term neonates and 100 mL/kg in preterm neonates) must be replaced, especially when the placenta is transected or abrupted during birth. In most cases, less than 10 to 20 mL/kg of volume restores mean arterial pressure to normal.

OTHER CAUSES OF HYPOTENSION

Hypoglycemia, hypocalcemia, and hypermagnesemia also cause hypotension in neonates. Hypotension induced by alcohol or magnesium intoxication usually responds to blood volume expansion or dopamine, or to both. Hypermagnesemic neonates generally respond to 100 to 200 mg/kg of calcium gluconate administered over a 5-minute period.[66]

MECONIUM

Meconium stained amniotic fluid (MSAF) when aspirated into the lungs during delivery or in utero can cause serious lung injury and respiratory distress syndrome (RDS). Most cases of meconium aspiration occur in utero; therefore, endotracheal intubation to suction the airway to remove MSAF should only occur if the neonate is distress: absent or depressed respirations, HR less than 100 bpm, or poor muscle tone.[66,74,75] A depressed MSAF stained infant should be intubated as soon as possible following delivery. Suctioning is accomplished through an ETT, and if there is a significant amount of MSAF or the infant remains in extremis, they should be transferred directly to the neonatal ICU.

COLOR

Essentially all neonates have a blue-tinged cast to their skin at birth. By 60 seconds of age, most of them are entirely pink, except for their hands and feet, which remain blue. If central cyanosis persists beyond 90 seconds of age, asphyxia, low cardiac output, pulmonary edema, methemoglobinemia, polycythemia, congenital heart disease, arrhythmias, and pulmonary disorders (e.g., respiratory distress, airway obstruction, hypoplastic lungs, diaphragmatic hernia) should be considered, especially if the infant remains cyanotic despite oxygen and controlled ventilation. Neonates who are pale at birth are often asphyxiated, hypovolemic, acidotic, or anemic, or they have congenital heart disease. A neonate whose skin is entirely pink within 2 minutes of birth may be intoxicated with alcohol or magnesium or may be alkalotic (pH >7.50). Rubrous neonates are usually polycythemic.

RESUSCITATION EQUIPMENT

Resuscitation beds should allow positioning of the neonate's head below the level of the lungs to promote drainage of lung fluid and reduce the likelihood of aspirating gastric contents. A servo-controlled infrared heater should be used to maintain the neonate's temperature between 36°C and 37°C, unless there is evidence of asphyxia. If asphyxia is noted, body temperature should be reduced to 34°C to 35°C for brain protection. A suction device should be available and should allow the suction pressure to be varied; pressures below −100 mm Hg should not be used.

Equipment required for tracheal intubation includes 0 and 00 straight laryngoscope blades; a pencil-type laryngoscope handle; 2.5-, 3.0-, and 3.5-mm ETTs; and a suction catheter that easily fits through each size tube. The ventilation system must permit ventilatory rates of at least 150 breaths/min and make it possible to maintain positive end expiratory pressure (PEEP). One-way valves can stick in the closed position, especially when high gas flow and high RRs are used. The modified Jackson-Rees or Ayres system works well when appropriately trained people use it. Overexpansion of the lungs with large tidal volumes injures the lungs and activates inflammatory processes that may cause chronic lung disease. Gentle inflation of the lung is less injurious to the lung. Airway inflation pressures should be measured continuously during assisted or controlled ventilation in the delivery room, and excessive pressures and tidal volumes should be avoided. As in any critical care situation, patient care should be guided by information. Consequently, blood gas and pH measurements are mandatory, and the results of these tests must be available within 10 minutes of drawing the blood sample. Umbilical arterial catheters are useful for measuring arterial blood pressure and withdrawing blood for blood gas analysis and pHa. They can also be used to infuse emergency fluids. Arterial oxygen saturation (SaO_2) can be measured immediately after birth by attaching a pulse oximeter to a hand or foot.[76] Pulse oximeters permit rapid detection of changes in oxygenation and rapid reduction of fraction of inspired oxygen (FiO_2). The normal SaO_2 of neonates is usually 87% to 95%, which is associated with a PaO_2 of 55 to 70 mm Hg.

PEDIATRIC CARDIAC ARREST AND RESUSCITATION

Pediatric cardiac arrest is not a rare event. At least 16,000 American children (8-20/100,000 children/year) suffer a cardiopulmonary arrest each year.[77-81] More than half of these cardiac arrests probably occur in-hospital.[77-82] With advances in resuscitation science and implementation techniques, survival from pediatric cardiac arrest has improved substantially over the past 25 years.[83]

Outcomes from pediatric cardiac arrest have improved significantly over the past 20 years. For example, survival to discharge from pediatric in-hospital cardiac arrest has increased from less than 10% in the 1980s[84,85] to greater than 25% in the 21st century. Of the pediatric patients that survive to hospital discharge, nearly three quarters will have favorable neurologic function defined by specific pediatric cerebral outcome measures and quality of life indicators.[83,86-88] Factors that influence outcome from pediatric cardiac arrest include (1) the pre-existing condition of the child; (2) the environment in which the arrest occurs; (3) the initial ECG rhythm detected; (4) the duration of no-flow time (the time during an arrest without spontaneous circulation or CPR); (5) the quality of the life-supporting therapies provided during the resuscitation; and (6) the quality of the life-supporting therapies during postresuscitation.

Not surprisingly, outcomes after pediatric out-of-hospital arrests are much worse than those after in-hospital arrests.[78,79,89-97] This may be due to the fact that there is a prolonged period of no flow in out-of-hospital arrests, where many of the pediatric cardiac arrests are not witnessed and only 30% of children are provided with bystander CPR. As a result of these factors, less than 10% of cases of pediatric out-of-hospital cardiac arrest (OHCA) survive to hospital discharge, and for those that do survive, severe neurological injury is common. These findings are especially troublesome, given that bystander CPR more than doubles patient survival rates in adults.[98] An exciting prospective, nationwide, population-based cohort study from Japan similarly demonstrates more than doubling of survival rates for children who have OHCA and receive bystander CPR either with conventional CPR (with rescue breathing) or chest compression only CPR compared with no bystander CPR.[99] The same study then further stratifies outcomes for OHCA into "cardiac" and "noncardiac" causes for arrest, and defines the relative value of rescue breathing during CPR by bystanders. Pediatric patients who have OHCA with noncardiac causes and receive bystander conventional CPR (including rescue breathing) had an association with higher frequency of favorable neurologic outcomes at 1 month after arrest compared with compression-only bystander CPR or no bystander CPR. For pediatric arrests defined as "cardiac" in nature, bystander CPR (conventional or compression-only) was associated with a higher rate of favorable neurologic outcomes 1 month after arrest compared with no bystander CPR. Interestingly, the two types of bystander CPR (conventional or compression-only) seemed to be similarly effective for pediatric cardiac arrests with cardiac causes, consistent with animal and adult studies.[99]

Survival outcomes after in-hospital cardiac arrest are higher in the pediatric population compared with adults; 27% of children survive to hospital discharge compared with only 17% of adults.[83] For both children and adults, outcomes are better after arrhythmogenic arrests, ventricular fibrillation (VF)/ventricular tachycardia (VT). Importantly, pediatric in-hospital arrests are less commonly caused by arrhythmias (10% of pediatric arrests vs. 25% of adult arrests), and approximately one-third of children and adults with these arrhythmogenic arrests survive to hospital discharge. Interestingly, the superior pediatric survival rate following in-hospital cardiac arrest reflects a substantially higher survival rate among children with asystole or pulseless electrical activity (PEA) compared with adults (24% vs. 11%). Further investigations have shown that the superior survival rate seen in children is mostly attributable to a much better survival rate among infants and preschool age children compared with older children.[87] Although speculative, the higher survival rates in children may be due to improved coronary and cerebral blood flow (CBF) during CPR because of increased chest compliance in these younger arrest victims, with improved aortic diastolic pressure and venous return.[100,101] In addition, survival of pediatric patients from an in-hospital cardiac arrest is more likely in hospitals staffed with dedicated pediatric physicians.[102]

Phases of Resuscitation

The four distinct phases of cardiac arrest and CPR interventions are (1) prearrest, (2) no flow (untreated cardiac arrest), (3) low flow (CPR), and (4) postresuscitation/arrest. Interventions to improve outcome of pediatric cardiac arrest should optimize therapies targeted to the time and phase of CPR, as suggested in Table 79.4.

TABLE 79.4 Phases of Cardiac Arrest and Resuscitation

Phase	Interventions
Prearrest phase (protect)	Optimize patient monitoring and rapid emergency response Recognize and treat respiratory failure or shock to prevent cardiac arrest
Arrest (no-flow) phase (preserve)	Minimize interval to BLS and ACLS Organize response with clear leadership Minimize interval to defibrillation, when indicated
Low-flow (CPR) phase (resuscitate)	Push hard, push fast Allow full chest recoil Minimized interruptions in compressions Avoid overventilation Titrate CPR to optimize myocardial blood flow (coronary perfusion pressures and exhaled CO_2) Consider adjuncts to improve vital organ perfusion during CPR Consider ECMO if standard CPR/ALS not promptly successful
Post-resuscitation phase: short-term	Optimize cardiac output and cerebral blood flow Treat arrhythmias, if indicated Avoid hyperglycemia, hyperthermia, hyperventilation Debrief to improve future responses to emergencies
Postresuscitation phase: long-term rehabilitation (regenerate)	Early intervention with occupational and physical therapy Bioengineering and technology interface Possible future role for stem cell transplantation

ACLS, Advanced cardiac life support; *ALS*, advanced life support; *BLS*, basic life support; *CPR*, cardiopulmonary resuscitation; *ECMO*, extracorporeal membrane oxygenation.

PREARREST

The prearrest phase refers to any relevant preexisting conditions of the child (e.g., neurologic, cardiac, respiratory, or metabolic problems) and precipitating events (e.g., respiratory failure or shock), uncoupling metabolic delivery and metabolic demand. Pediatric patients who suffer an in-hospital cardiac arrest often have changes in their physiological status in the hours leading up to their arrest event.[103,104] Therefore, interventions during the prearrest phase focus on preventing the cardiac arrest, with special attention to early recognition and targeted treatment of respiratory failure and shock. Early recognition plays a key role in identifying a prearrest state in children, who unlike adults may be able to mount a prolonged physiologic response to a worsening clinical picture. Medical emergency teams (METs; also known as *rapid response teams*) are in-hospital emergency teams designed specifically for this purpose. Frontline providers, and even parents, are encouraged to initiate evaluation by METs based on physiologic protocol driven parameters or even intuition. Patients are assessed by the METs, and those at high risk of clinical decompensation are transferred to a pediatric ICU if necessary, with the goal to prevent progression to full cardiac arrest or to decrease the response time to initiation of advanced life support, thereby limiting the no-flow state. Implementation of METs decreases the frequency of cardiac arrests compared with retrospective control periods before MET initiation.[105-107] While early recognition protocols cannot identify all children at risk for cardiac arrest, it seems reasonable to assume that transferring critically ill children to an ICU early in their disease process for better monitoring and more aggressive interventions can improve resuscitative care and clinical outcomes. The caveat is that prearrest states must be identified to initiate monitoring and interventions that may inhibit the progression to an arrest. While a significant amount of research dollars and resources are spent on the other phases of cardiac arrest, particular focus on the prearrest state may yield the greatest improvement in survival and neurologic outcomes.

NO FLOW/LOW FLOW

Airway-Breathing-Circulation or Circulation-Airway-Breathing

For OHCA victims, "compression-only" CPR has been associated with improved outcomes.[108,109] This is now the recommended modality for emergency medical service dispatcher instructing bystander CPR.[110] In a recent Japanese study, children with OHCA due to a primary cardiac etiology displayed an equivalent survival rate between compression-only CPR and classic CPR with rescue breaths. However, only 29% of patients had a cardiac cause of OHCA. Those with noncardiac etiology in the overall cohort had a significantly worse survival rate with compression-only CPR, as compared with classic CPR with rescue breaths.[111] Additionally, in another nationwide Japanese OHCA registry study, compression-only CPR was superior to no bystander CPR at all but not to conventional CPR.[112] In a recent American OHCA registry study, children who received conventional bystander CPR with chest compressions and rescue breaths had improved rates of overall survival and survival with favorable outcomes as compared with those who did not receive CPR, whereas those receiving compression-only CPR did not fare any better than children not receiving CPR.[113] Thus compression-only CPR is not recommended for children in either the inpatient or out-of-hospital setting, except in situations in which "rescuers are unwilling or unable to deliver breaths."[114]

Regardless, the prioritization of initial interventions during CPR has shifted from airway-breathing-circulation ("A-B-C") to circulation-airway-breathing ("C-A-B") in order to prevent harmful delays in the initiation of chest compressions and due to the relative complexity of the tasks involved in providing assisted ventilation. This is endorsed by both the 2010 and 2015 AHA BLS Guidelines.[114,115] However, a 2015 International Liaison Committee on Resuscitation consensus statement identified a paucity of pediatric-specific evidence to support this recommendation.[116] In our opinion, the approach is physiologically sound, especially given the association of delayed chest compression initiation with poor outcomes. With that said, the pediatric provider must consider the predominance of asphyxia and hypoxemia as precursors to cardiac arrest.[83,117] This is especially true in the ICU and operating room, where personnel and other resources frequently allow for simultaneous circulatory support with high-quality chest compressions as well as the provision of assisted ventilations by experienced personnel.

In order to improve outcomes from pediatric cardiac arrest, it is imperative to shorten the no-flow phase of untreated cardiac arrest. To that end, it is important to monitor high-risk patients to allow early recognition of the cardiac arrest and prompt initiation of basic and advanced life support. Effective CPR optimizes coronary perfusion pressure (by elevating aortic diastolic pressure relative to RAP) and cardiac output to critical organs to support vital organ viability (by elevating mean aortic pressure) during the low flow phase. Important tenets of basic life support are *push hard, push fast, allow full chest recoil between compressions, and minimize interruptions of chest compression*. The myocardium receives blood flow from the aortic root, mainly during diastole, via the coronary arteries. When the heart arrests and no blood flows through the aorta, coronary blood flow ceases. However, during chest compressions, aortic pressure rises at the same time as RAP and with the subsequent decompression phase of chest compressions, the RAP falls faster and lower than the aortic pressure, which generates a pressure gradient that perfuses the heart with oxygenated blood. Therefore, full elastic recoil (release) is critical to create a pressure difference between the aortic root and the right atrium. A CPP below 15 mm Hg during CPR is a poor prognostic factor for ROSC. Achieving optimal coronary perfusion pressure, exhaled carbon dioxide concentration, and cardiac output during the low flow phase of CPR is consistently associated with an improved chance for return of spontaneous circulation (ROSC) and improved short- and long-term outcome in mature animal and human studies.[118-125] There is a critical need for research evaluating goal directed CPR, both in immature animal models and pediatric patients. Other measures essential for truncating the no-flow phase during VF and pulseless VT are rapid detection and prompt defibrillation. Clearly, CPR alone is inadequate for successful resuscitation from these arrhythmias. For cardiac arrests resulting from asphyxia and/or ischemia, provision of adequate myocardial perfusion and myocardial oxygen delivery are the critical elements for ROSC.

POSTARREST/RESUSCITATION

The postarrest/resuscitation phase includes coordinated, skilled management of the immediate post-resuscitation stage, the next few hours to days, and long-term rehabilitation. The immediate post-resuscitation stage is a high-risk period for ventricular arrhythmias and other reperfusion injuries. Goals of interventions implemented during the immediate post-resuscitation stage and the next few days include adequate tissue oxygen delivery, treatment of post-resuscitation myocardial dysfunction, and minimizing post-resuscitation tissue injury (e.g., preventing post-resuscitation hyperthermia and hypoglycemia; and, perhaps initiating post-resuscitation therapeutic hypothermia, preventing hyperglycemia and avoiding hyperoxia). This post-arrest/resuscitation phase may have the greatest potential for innovative advances in the understanding of cell injury (excitotoxicity, oxidative stress, metabolic stress) and cell death (apoptosis and necrosis), ultimately leading to novel molecular-targeted interventions. The rehabilitation stage concentrates on salvage of injured cells, and support for reengineering of reflex and voluntary communications of these cell and organ systems to improve long-term functional outcome.

The specific phase of resuscitation dictates the focus of care. Interventions that improve outcome during one phase may be deleterious during another. For instance, intense vasoconstriction during the low flow phase of cardiac arrest improves coronary perfusion pressure and the probability of ROSC. The same intense vasoconstriction during the post-resuscitation phase increases left ventricular afterload and may worsen myocardial strain and dysfunction. Current understanding of the physiology of cardiac arrest and recovery allows us to only crudely manipulate blood pressure, oxygen delivery and consumption, body temperature, and other physiologic parameters in our attempts to optimize outcome. Future strategies likely will take advantage of increasing knowledge of cellular injury, thrombosis, reperfusion, mediator cascades, cellular markers of injury and recovery, and transplantation technology, including stem cells.

Interventions During the Cardiac Arrest (No Flow) and Cardiopulmonary Resuscitation (Low Flow)

AIRWAY AND BREATHING

During CPR, cardiac output and pulmonary blood flow are ~10% to 25% of that during normal sinus rhythm; therefore, a lower minute ventilation is necessary for adequate gas exchange from the blood traversing the pulmonary circulation. Animal and adult data indicate that overventilation ("overventilation" from exuberant rescue breathing) during CPR is common and can substantially compromise venous return and subsequently cardiac output.[126-128] These detrimental hemodynamic effects are compounded when one considers the effect of interruptions in CPR to provide airway management and rescue breathing and may contribute to worse survival outcomes.[129-132] While overventilation is problematic, in light of the fact that most pediatric arrests are asphyxial in nature, immediate initiation of *adequate* ventilation is still important. The difference between arrhythmogenic and asphyxial arrests lies in the physiology. In animal models of sudden VF cardiac arrest, acceptable PaO_2 and $PaCO_2$ persist for 4 to 8 minutes during chest compressions without rescue breathing.[133,134] This is in part because aortic oxygen and carbon dioxide concentrations at the onset of the arrest do not vary much from the prearrest state with no blood flow and minimal aortic oxygen consumption. The lungs act as a reservoir of oxygen during the low-flow state of CPR; therefore, adequate oxygenation and ventilation can continue without rescue breathing. Several retrospective studies of witnessed VF cardiac arrest in adults have also shown that outcomes are similar after bystander-initiated CPR with either chest compressions alone or chest compressions plus rescue breathing.[135] However, during asphyxial arrest, peripheral and pulmonary blood flow continues during the prearrest, state resulting in significant arterial and venous oxygen desaturation, elevated lactate levels, and depletion of the pulmonary oxygen reserve. Therefore, at the onset of CPR, there is substantial arterial hypoxemia and resulting acidemia. In this circumstance, rescue breathing with controlled ventilation can be a life-saving maneuver. In contrast, the adverse hemodynamic effects from overventilation during CPR combined with possible interruptions in chest compressions to open the airway and deliver rescue breathing are a lethal combination in certain circumstances such as VT/VF arrests. In short, the resuscitation technique should be titrated to the physiology of the patient to optimize patient outcome.

CIRCULATION: OPTIMIZING BLOOD FLOW DURING LOW FLOW CARDIOPULMONARY RESUSCITATION: PUSH HARD, PUSH FAST

When the heart arrests, no blood flows to the aorta and coronary blood flow ceases immediately.[135] At that point, provision of high quality CPR (PUSH HARD, PUSH FAST) is vital to reestablish coronary flow. The goal during CPR is to maximize the myocardial perfusion pressure (MPP). Related by the following equation: MPP = aortic diastolic blood pressure (AoDP) minus RAP, myocardial blood flow improves as the gradient between AoDP and RAP increases. During downward compression phase, aortic pressure rises at the same time as RAP with little change in the MPP. However, during the decompression phase of chest compressions, the RAP falls faster and lower than the aortic pressure, which generates a pressure gradient perfusing the heart with oxygenated blood during this artificial period of "diastole." Several animal and human studies have demonstrated, in both VT/VF and asphyxial models, the importance of establishing MPP as a predictor for short-term survival outcome (ROSC).[124,136-139] Because there is no flow without chest compressions, it is important to minimize interruptions in chest compressions. To allow good venous return in the decompression phase of external cardiac massage, it is also important to allow full chest recoil and to avoid overventilation (preventing adequate venous return because of increased intrathoracic pressure).

Based on the provided equation, MPP can be improved by strategies that increase the pressure gradient between the aorta and the right atrium. As an example, the inspiratory impedance threshold device (ITD) is a small, disposable valve that can be connected directly to the tracheal tube or face mask to augment negative intrathoracic pressure during the inspiratory phase of spontaneous breathing and the decompression phase of CPR by impeding airflow into the lungs. Application in animal and adult human trials of CPR has established the ability of the ITD to improve vital organ perfusion pressures and myocardial blood flow[140-145]; however, in the only randomized trial during adult CPR, mortality benefit was limited to the subgroup of patients with PEA.[145] Additional evidence that augmentation of negative intrathoracic pressure can improve perfusion pressures during CPR comes from the active compression-decompression device (ACD). The ACD is a handheld device that is fixed to the anterior chest of the victim by means of suction similar to a household plunger that can be used to apply active decompression forces during the release phase, thereby creating a vacuum within the thorax. By actively pulling during the decompression phase, blood is drawn back into the heart by the negative pressure.[146] Animal and adult studies have demonstrated that the combination of ACD with ITD act in concert to further improve perfusion pressures during CPR compared with ACD alone.[142] In the end, while novel interventions such as the ITD and ACD are promising adjuncts to improve blood flow during CPR, the basic tenants of PUSH HARD, PUSH FAST, ALLOW FULL CHEST WALL RELEASE, MINIMIZE INTERRUPTIONS, and DON'T OVERVENTILATE are still the dominate factors to improve blood flow during CPR and chance of survival.

CHEST COMPRESSION DEPTH

The pediatric chest compression depth recommendation of at least one-third anterior-posterior chest depth (approximately 4 cm in infants and 5 cm in children) is based largely upon expert clinical consensus, using data extrapolated from animal, adult, and limited pediatric data. In a small study of six infants, chest compressions targeted to one half anterior-posterior chest depth resulted in improved systolic blood pressures, compared with those targeted at one-third anterior-posterior chest depth.[147] While only a small series with qualitatively estimated chest compression depths, this is the first study to collect actual data from children supporting the existing chest compression depth guidelines. On the contrary, two recent studies using computer automated tomography (CT)[148,149] suggest that depth recommendations based on a relative (%) anterior-posterior chest compression depth are deeper than that recommended for adults, and that a depth of one half anterior-posterior chest depth will result in direct compression to the point of fully emptying the heart and requisite shifting of heart because of inadequate AP diameter reserve in most children. Future studies that collect data from actual children and that associate quantitatively measured chest compression depths with short- and long-term clinical outcomes (arterial blood pressure, end tidal carbon dioxide, ROSC, survival) are needed.

COMPRESSION/VENTILATION RATIOS

The amount of ventilation provided during CPR should match, but not exceed, perfusion and should be titrated to the amount of circulation during the specific phase of resuscitation, as well as the metabolic demand of the tissues. Therefore, during the low flow state of CPR when the amount of cardiac output is roughly 10% to 25% of normal, less ventilation is needed.[150] However, the best ratio of compressions to ventilations in pediatric patients is largely unknown and depends on many factors, including the compression rate, the tidal volume, the blood flow generated by compressions, and the time that compressions are interrupted to perform ventilation. Recent evidence demonstrates that a compression/ventilation ratio of 15:2 delivers the same minute ventilation and increases the number of delivered chest compressions by 48% compared with CPR at a compression/ventilation ratio of 5:1 in a simulated pediatric arrest model.[151,152] This is important because when chest compressions cease, the aortic pressure rapidly decreases and coronary perfusion pressure falls precipitously, thereby decreasing myocardial oxygen delivery.[135] Increasing the ratio of compressions to ventilations minimizes these interruptions, thus increasing coronary blood flow. The benefits of PPV (increased arterial content of oxygen and carbon dioxide elimination) must be balanced against the adverse consequence of decreased circulation. These findings are in part the reason the AHA now *recommends a pediatric compression/ventilation ratio of 15:2*.

DUTY CYCLE

In a model of human adult cardiac arrest, cardiac output and coronary blood flow are optimized when chest compressions last for 30% of the total cycle time (approximately 1:2 ratio of time in compression to time in relaxation).[153] As the duration of CPR increases, the optimal duty cycle may increase to 50%. In a juvenile swine model, a relaxation period of 250 to 300 milliseconds (duty cycle of 40%-50% at a compression rate of 120/min) correlates with improved cerebral perfusion pressures (CPPs) compared with shorter duty cycles of 30%.[154]

CIRCUMFERENTIAL VERSUS FOCAL STERNAL COMPRESSIONS

In adult and animal models of cardiac arrest, circumferential (vest) CPR has been demonstrated to dramatically improve CPR hemodynamics.[155] In smaller infants, it is often possible to encircle the chest with both hands and depress the sternum with the thumbs, while compressing the thorax circumferentially (thoracic squeeze). In an infant animal model of CPR, this “two-thumb” method of compression with thoracic squeeze resulted in higher systolic and diastolic blood pressures and a higher pulse pressure than traditional two-finger compression of the sternum.[156] Although not rigorously studied, our clinical experience indicates that it is very difficult to attain adequate chest compression force and adequate aortic pressures with the two-finger technique, so we fully support the AHA Guidelines for health care providers to perform CPR on infants with the two-thumb-encircling hands technique.[157]

OPEN-CHEST CARDIOPULMONARY RESUSCITATION

In animal models, high quality standard, closed-chest CPR generates myocardial blood flow that is greater than 50% of normal, CBF that is approximately 50% of normal, and cardiac output ~10% to 25% of normal.[135,155,158,159] By contrast, open-chest CPR can generate myocardial and CBF that approaches normal. Although open-chest massage improves coronary perfusion pressure and increases the chance of successful defibrillation in animals and humans,[160-162] performing a thoracotomy to allow open-chest CPR is impractical in many situations. A retrospective review of 27 cases of CPR following pediatric blunt trauma (15 with open-chest CPR and 12 with closed-chest CPR) demonstrated that open-chest CPR increased hospital cost without altering rates of ROSC or survival to discharge. However, survival in both groups was 0%, indicating that the population may have been too severely injured or too late in the process to benefit from this aggressive therapy.[163] Open-chest CPR is often provided to children after open-heart cardiac surgery and sternotomy. Earlier institution of open-chest CPR may warrant reconsideration in selected special resuscitation circumstances.

MEDICATIONS USED TO TREAT CARDIAC ARREST

While animal studies have indicated that epinephrine can improve initial resuscitation success after both asphyxial and VF cardiac arrests, there are no prospective studies to support the use of epinephrine or any other medication to improve survival outcome from pediatric cardiac arrest. A variety of medications are used during pediatric resuscitation attempts, including vasopressors (epinephrine and vasopressin), antiarrhythmics (amiodarone and lidocaine), and other drugs such as calcium chloride and sodium bicarbonate. Each will be discussed separately as follows.

Vasopressors

Epinephrine (adrenaline) is an endogenous catecholamine with potent α- and β-adrenergic stimulating properties. The α-adrenergic action (vasoconstriction) increases systemic and PVR. The resultant higher aortic diastolic blood pressure improves coronary perfusion pressure and myocardial blood flow, even though it reduces global cardiac output during CPR; as noted previously, adequacy of myocardial blood flow is a critical determinant of ROSC. Epinephrine also increases CBF during good quality CPR because peripheral vasoconstriction directs a greater proportion of flow to the cerebral circulation.[164-166] However, recent evidence suggests that epinephrine can decrease local cerebral microcirculatory blood flow at a time when global cerebral flow is increased.[167] The β-adrenergic effect increases myocardial contractility and HR, and relaxes smooth muscle in the skeletal muscle vascular bed and bronchi; however, the β-adrenergic effects are not observed in the peripheral vascular beds secondary to the high dose used in cardiac arrest. Epinephrine also increases the vigor and intensity of VF, increasing the likelihood of successful defibrillation. High-dose epinephrine (0.05-0.2 mg/kg) improves myocardial and CBF during CPR more than standard-dose epinephrine (0.01-0.02 mg/kg) in animal models of cardiac arrest and may increase the incidence of initial ROSC.[168,169] However, prospective and retrospective studies have indicated that the use of high-dose epinephrine in adults or children does not improve survival and may be associated with worse neurologic outcome.[170,171] A randomized, blinded, controlled trial of rescue high-dose epinephrine versus standard-dose epinephrine after failed initial standard dose epinephrine in pediatric in-hospital cardiac arrest demonstrated a worse 24-hour survival in the high-dose epinephrine group (1 of 27 survivors vs. 6 of 23 survivors, $P < .05$).[172] Based on these clinical studies, high-dose epinephrine cannot be recommended routinely for either initial or rescue therapy. Importantly, these studies indicate that high-dose epinephrine can worsen a patient's post-resuscitation hemodynamic condition and likelihood of survival.

Vasopressin is a long-acting endogenous hormone that acts at specific receptors to mediate systemic vasoconstriction (V_1 receptor) and reabsorption of water in the renal tubule (V_2 receptor). Vasoconstrictive properties are most intense in the skeletal muscle and skin vascular beds. Unlike epinephrine, vasopressin is not a pulmonary vasoconstrictor. In experimental models of cardiac arrest, vasopressin increases blood flow to the heart and brain and improves long-term survival compared with epinephrine. However, vasopressin can decrease splanchnic blood flow during and following CPR and can increase afterload in the post-resuscitation period placing further strain on the left ventricle.[158,173-176] Adult randomized, controlled trials suggest that outcomes are similar after use of vasopressin or epinephrine during CPR.[177,178] During pediatric arrest, a case series of four children who received vasopressin during six prolonged cardiac arrest events suggested that the use of bolus vasopressin may result in ROSC when standard medications have failed.[179] However, a more recent retrospective study of 1293 consecutive pediatric arrests from the National Registry of CPR (NPCRP) found that vasopressin use, while infrequent (administered in only 5% of events), was associated with a lower likelihood of ROSC. Therefore, it is unlikely that vasopressin will replace epinephrine as a first-line agent in pediatric cardiac arrest. However, the available data suggest that its use in conjunction with epinephrine may deserve further investigation, especially in prolonged arrest unresponsive to initial epinephrine resuscitation.

Antiarrhythmic Medications

Calcium. Calcium is used frequently in cases of pediatric cardiac arrest, despite the lack of evidence for efficacy. In the absence of a documented clinical indication (i.e., hypocalcemia, calcium channel blocker overdose, hypermagnesemia, or hyperkalemia), administration of calcium does not improve outcomes from cardiac arrest.[180-188] To the contrary, three pediatric studies have suggested a potential for harm, as routine calcium administration was associated with decreased survival rates and / or worse neurological outcomes.[180-188] Despite limited clinical data to support the use of calcium during CPR, it is reasonable to consider calcium administration during CPR for cardiac arrest patients at high risk of hypocalcemia (e.g., renal failure, shock associated with massive transfusion, etc.).

Buffer Solutions. There are no randomized controlled studies in children examining the use of sodium bicarbonate for management of pediatric cardiac arrest. Two randomized controlled studies have examined the value of sodium bicarbonate in the management of adult cardiac arrest[189] and in neonates with respiratory arrest in the delivery room.[190] Neither study was associated with improved survival. In fact, one multicenter retrospective in-hospital pediatric study found that sodium bicarbonate administered during cardiac arrest was associated with decreased survival, even after controlling for age, gender and first documented cardiac rhythm.[187] Therefore, during pediatric cardiac arrest resuscitation, the routine use of sodium bicarbonate is not recommended. Clinical trials involving critically ill adults with severe metabolic acidosis do not demonstrate a beneficial effect of sodium bicarbonate on hemodynamics despite correction of acidosis.[191-192] This is somewhat surprising in light of data that severe acidosis may depress the action of catecholamines and worsen myocardial function.[193,194] Nevertheless, the common use of sodium bicarbonate during CPR is not supported by clinical data. Pediatric patients with implanted cardiac pacemakers may have an increased threshold for myocardial electrical stimulation when acidotic[195]; therefore, administration of bicarbonate or another buffer is appropriate for management of severe documented acidosis in these children. Administration of sodium bicarbonate also is indicated in the patient with a tricyclic antidepressant overdose, hyperkalemia, hypermagnesemia, or sodium channel blocker poisoning. The buffering action of bicarbonate occurs when a hydrogen cation and a bicarbonate anion combine to form carbon dioxide and water. Carbon dioxide must be cleared through adequate minute ventilation; thus, if ventilation is impaired during sodium bicarbonate administration, carbon dioxide buildup may negate the buffering effect of bicarbonate. Because carbon dioxide readily penetrates cell membranes, intracellular acidosis may paradoxically increase after sodium bicarbonate administration without adequate ventilation. Therefore, bicarbonate should not be used for management of respiratory acidosis.

Unlike sodium bicarbonate, tromethamine (THAM) buffers excess protons without generating carbon dioxide; in fact, carbon dioxide is consumed following THAM administration. In a patient with impaired minute ventilation, tromethamine may be preferable when buffering is necessary to mitigate severe acidosis. Tromethamine undergoes renal elimination, and renal insufficiency may be a relative contraindication to its use. Carbicarb, an equimolar combination of sodium bicarbonate and sodium carbonate, is another buffering solution that generates less carbon dioxide than sodium bicarbonate. In a canine model of cardiac arrest comparing animals given normal saline, sodium bicarbonate, THAM, or Carbicarb, the animals given any buffer solution had a higher rate of ROSC than the animals given normal saline. In the animals given sodium bicarbonate or Carbicarb, the interval to ROSC was significantly shorter than in animals given normal saline. However, at the end of the 6-hour study period, all resuscitated animals were in a deep coma, so no inferences regarding meaningful survival can be drawn.[196] It is premature to recommend either THAM or Carbicarb during CPR at this time.

POST-RESUSCITATION INTERVENTIONS

Temperature Management

Two seminal articles[197,198] have established that induced hypothermia (32°C-34°C) could improve outcome for comatose adults after resuscitation from VF cardiac arrest. In both randomized, controlled trials, the inclusion criteria were patients older than 18 years who were persistently comatose after successful resuscitation from nontraumatic VF.[199,200] However, in a recent randomized control trial with unconscious adult survivors of OHCA, a targeted temperature of 33°C did not confer a benefit as compared with the targeted temperature of 36°C.[201] Interpretation and extrapolation of these studies to children is difficult; however, fever within the first 48 hours following cardiac arrest, brain trauma, stroke, and ischemia is associated with poor neurologic outcome. Emerging neonatal trials of selective brain cooling and systemic cooling show promise in neonatal HIE, suggesting that induced hypothermia may improve outcomes.[202,203] The efficacy of therapeutic hypothermia following pediatric cardiac arrest is being evaluated in a randomized controlled trial (clinicaltrials.gov identifier NCT00880087); THAPCA: Therapeutic Hypothermia After Pediatric Cardiac Arrest (www.thapca.org). At a minimum, it is advisable to avoid hyperthermia in children following CPR. Using an approach of "therapeutic normothermia" with scheduled administration of antipyretic medications and the use of external cooling devices, while monitoring core temperature, may be necessary to prevent hyperthermia in this population. Notably, preventing hyperthermia is not easy. Many children become hyperthermic post-arrest despite the intent to prevent hypothermia.[198]

Glucose Control

Both hyperglycemia and hypoglycemia following cardiac arrest is associated with worse neurologic outcome.[204-207] While it seems intuitive that hypoglycemia would be associated with worse neurologic outcome, whether hyperglycemia per se is harmful or is simply a marker of the severity of the stress hormone response from prolonged ischemia is not clear. A recent randomized control trial suggests that tight glycemic control in critically ill children had no effect on major clinical outcomes, but was associated with a higher incidence of hypoglycemia.[208] In summary, there is insufficient evidence to formulate a strong recommendation on the management of hyperglycemia in children with ROSC following cardiac arrest. If hyperglycemia is treated following ROSC in pediatric patients, blood glucose concentrations should be carefully monitored to avoid hypoglycemia.

Blood Pressure Management

A patient with ROSC may have substantial variability in blood pressure following cardiac arrest. Postarrest/resuscitation myocardial dysfunction is very common and is often associated with hypotension (discussed later).[199,200,209-218] In addition, hypertension may occur, especially if the patient receives vasoactive infusions for postarrest myocardial dysfunction. Optimization of blood pressure postarrest is critical to maintain adequate perfusion pressure to vital organs that may have already been injured from the "no flow" and "low blood flow" states during initial cardiac arrest and CPR. Cerebral blood flow in healthy patients is tightly controlled over a wide range of mean arterial blood pressure via cerebral neurovascular bundle (autoregulation); however, adults resuscitated from cardiac arrest have demonstrated impaired autoregulation of CBF, and this may also be the case in children.[219] Dysautoregulation of the cerebral neurovascular bundle following cardiac arrest may limit the brain's ability to regulate excessive blood flow and microvascular perfusion pressure, thereby leading to reperfusion injury during systemic hypertension. However, in animal models, brief induced hypertension following resuscitation results in improved neurologic outcome compared with normotensive reperfusion.[220,221] Conversely, systemic hypotension may perpetuate neurologic metabolic crisis following ischemic injury by uncoupling bioenergetic demand and delivery. Therefore, a practical approach to blood pressure management following cardiac arrest is to attempt to minimize blood pressure variability in this high-risk period following resuscitation.

Post-resuscitation Myocardial Dysfunction

Postarrest myocardial stunning and arterial hypotension occur commonly after successful resuscitation in both animals and humans.[199,200,209-218] Animal studies demonstrate that postarrest myocardial stunning is a global phenomenon with biventricular systolic and diastolic dysfunction. Postarrest myocardial stunning is pathophysiologically and physiologically similar to sepsis-related myocardial dysfunction and postcardiopulmonary bypass myocardial dysfunction, including increases in inflammatory mediators and NO production.[212,215,218,216] Because cardiac function is essential to reperfusion following cardiac arrest, management of postarrest myocardial dysfunction may be important to improving survival. The classes of agents used to maintain circulatory function (i.e., inotropes, vasopressors, and vasodilators) must be carefully titrated during the post-resuscitation phase to the patient's cardiovascular physiology. Although the optimal management of post–cardiac arrest hypotension and myocardial dysfunction has not been established, data suggest that aggressive hemodynamic support may improve outcomes. Controlled trials in animal models have shown that dobutamine, milrinone, levosimendan can effectively ameliorate post–cardiac arrest myocardial dysfunction.[209,210,222,223] In clinical observational studies, fluid resuscitation has been provided for patients with hypotension and concomitant low central venous pressure, and various vasoactive infusions, including epinephrine, dobutamine, and dopamine, have been used to treat the myocardial dysfunction syndrome.[199,200,213-217] In the end, optimal use of these agents involves close goal-directed titration, and the use of invasive hemodynamic monitoring may be appropriate. General critical care principles suggest that appropriate therapeutic goals are adequate blood pressures and adequate oxygen delivery. However, the definition of "adequate" is elusive. Reasonable interventions for vasodilatory shock with low central venous pressure include fluid resuscitation and vasoactive infusions. Appropriate considerations for left ventricular myocardial dysfunction include euvolemia, inotropic infusions, and afterload reduction.

NEUROMONITORING

Continuous neuromonitoring and goal-directed intervention following cardiac arrest is an exciting frontier with great promise in improving neurologic outcomes post–cardiac arrest.[224] Continuous electroencephalogram (cEEG) monitoring is an increasingly instituted modality for neuromonitoring of critically ill patients, especially to diagnose nonconvulsive seizures (NCS) and seizures in patient's receiving muscle relaxants. cEEG monitoring is noninvasive, performed at the bedside, and permits continuous assessment of cortical function. Interpretation of continuous electroencephalogram (EEG) is usually performed by a neurologist from a remote location, and not bedside critical care physicians. However, advances in quantitative EEG tools may allow bedside caregivers to identify important electrographic events, such as seizures or abrupt background changes, to potentially permit real-time analysis and intervention.[225] In a prospective study of cEEG in children, NCS were detected in 39% (12 of 31) children following cardiac arrest.[226] In a partially overlapping cohort of 19 children, NCS were common in children undergoing therapeutic hypothermia after cardiac arrest.[226] NCS seems to be a common occurrence following cardiac arrests in children. Although the relationship of NCS to worse outcomes has not been established in pediatric patients following cardiac arrest, it has been associated with worse outcomes among critically ill adults and neonates.[227-233] We believe that cEEG should be considered for children post–cardiac arrest and that patients with NCS (especially status epilepticus with NCS) should be treated with anticonvulsant medication. Further study is warranted to better establish frequency of NCS and potential benefit in outcomes with anticonvulsant therapy.

Oxidative injury may be greatest in the early phases of post-resuscitation therapy following cardiac arrest.[234] Interestingly, the use of 100% oxygen (compared with room air) during and immediately following resuscitation in animal models may potentiate oxidative injury to key mitochondrial enzymes (pyruvate dehydrogenase or manganese superoxide) or mitochondrial lipids (cardiolipin), and is associated with worse neurologic outcomes.[235-238] Experimental protocols in large animals using peripheral pulse-oximetry to titrate oxygenation in the post-resuscitation phase can reduce post-resuscitation hyperoxia and significantly improve neuropathology and neurobehavioral outcomes.[239] Consistent with these experimental findings, arterial hyperoxia ($PaO_2 \geq 300$ mm Hg) was independently associated with in-hospital mortality compared with either hypoxia or normoxia in an observational study among critically ill adult patients admitted to the ICU within 24 hours of a cardiac arrest.[240] We believe it is prudent to titrate oxygenation during and following pediatric cardiac arrest. Although the optimal SpO_2 is not known, we recommend titration of FiO_2 to the lowest amount necessary to assure $SpO_2 > 94\%$. Perhaps the future of post-arrest care will include more aggressive neurocritical care monitoring, such as near infrared spectroscopy, cerebral microdialysis, $PbtO_2$, CBF, and even bedside analysis of mitochondrial dysfunction.

QUALITY OF CARDIOPULMONARY RESUSCITATION

Despite evidence-based guidelines, extensive provider training, and provider credentialing in resuscitation medicine, the quality of CPR is typically poor. CPR guidelines recommend target values for selected CPR parameters related to rate and depth of chest compressions and ventilations, avoidance of CPR-free intervals, and complete release of sternal pressure between compressions.[241] Slow compression rates, inadequate depth of compression, and substantial pauses are the norm. An approach to *Push Hard, Push Fast, Minimize Interruptions, Allow Full Chest Recoil, and Don't Overventilate* can markedly improve myocardial, cerebral, and systemic perfusion, and will likely improve outcomes.[131] Quality of post-resuscitative management has also been demonstrated to be critically important to improve resuscitation survival outcomes.[213] Measuring the quality of CPR and avoiding overventilation during cardiac arrest resuscitation have recently been reemphasized by consensus of the International Liaison Committee on Resuscitation and the AHA.[242] Although the correct amount, timing, intensity, and duration of ventilation that is required during CPR is controversial, there is no controversy that measurement and titration of the amount of ventilation to the amount of blood perfusion are desirable. Thus additional technology that is safe, accurate, and practical would improve detection and feedback of the "quality of CPR."

Recent technology has been developed that monitors quality of CPR by force sensors and accelerometers, and can provide verbal feedback to the CPR administrator regarding the frequency and depth of chest compressions and the volume of ventilations. Recent pediatric data illustrates that intensive training and real-time corrective feedback can help chest compression quality approach age-specific AHA CPR guideline targets.[243-245] Moreover, improvements in post-resuscitation care can improve resuscitation survival outcomes.[213]

EXTRACORPOREAL MEMBRANE OXYGENATION-CARDIOPULMONARY RESUSCITATION

The use of extracorporeal membrane life-saving (ECLS) devices as a rescue therapy for refractory cardiac arrest (ECPR) is an exciting topic in resuscitation science. In children with medical or surgical cardiac diseases, ECPR has been shown to improve survival to hospital discharge[246] and can be effective after even greater than 50 minutes of CPR.[247] However, at this time, observational data has not consistently demonstrated a survival benefit of ECPR compared with conventional CPR across broad populations.[248,249] Children with primary cardiac disease may have a survival advantage, due to these disease processes being amenable to a bridge with ECLS—whether to recovery, surgery, or transplantation. There may be an underlying advantage for these patients as well, stemming from predominantly single-organ failure compared with patients with noncardiac etiologies of cardiac arrest, allowing for a greater chance of full recovery after resuscitation.[250] Importantly, in these observational studies, ECPR is used as a rescue therapy in patients who likely would have died with continued conventional resuscitation efforts.[250] In fact, in a GWTG-R study that looked at both cardiac and noncardiac patients with greater than 10 minutes of CPR, those who received ECPR had improved survival and favorable neurologic outcome at discharge.[251] A lack of survival advantage, even when controlling for confounding factors, is flawed by the nature of these studies.[252] In the absence of randomized controlled trials that specifically compare early initiation of ECPR and conventional CPR, it is probably reasonable to consider ECPR as a rescue therapy in patients with potentially reversible underlying disease processes. However, as noted in PALS guidelines, any reasonable chance of success requires a setting with "existing ECMO protocols, expertise, and equipment,"[253] and dedicated teams that train for efficient cannulation under difficult circumstances. Therefore, timely, quality E-CPR may be an exciting adjuvant to conventional CPR for pediatric patients. Future frontiers will define patient populations and optimize the clinical approach to extracorporeal support; however, clinicians providing CPR should consider E-CPR early in the course of a resuscitation not responding to conventional CPR. Perhaps after failure to attain ROSC within 5 minutes, clinicians should ask themselves: (1) does the patient have a potentially reversible process, (2) would ECMO be a "bridge" to a potentially good outcome, and (3) do we have the personnel and resources to provide EMCO promptly? If the answer to all three are "yes," prompt implementation of E-CPR should be considered. We believe that patients arriving with a witnessed arrest with immediate initiation of CPR *and* evidence of quality CPR should be considered E-CPR candidates.

Ventricular Fibrillation and Ventricular Tachycardia in Children

Pediatric VF, or VT, has been an underappreciated pediatric problem. Recent studies indicate that VF and VT (i.e., shockable rhythms) occur in 27% of in-hospital cardiac arrests at some time during the resuscitation.[254] In a population of pediatric cardiac ICU patients, as many as 41% of arrests were associated with VF or VT.[255] According to the National Registry of Cardiopulmonary Resuscitation (NRCPR) database, 10% of children with in-hospital cardiac arrest had an initial rhythm of VF/VT. In all, 27% of the children had VF/VT at some time during the resuscitation.[254] The incidence of VF varies by setting and age.[256] In special circumstances, such as tricyclic antidepressant overdose, cardiomyopathy, post–cardiac surgery, and prolonged QT syndromes, VF and pulseless VT are more likely. The treatment of choice for short-duration VF is prompt defibrillation. In general, the mortality rate increases by 7% to 10% per minute of delay to defibrillation. Because VF must be considered before defibrillation can be provided, early determination of the rhythm by ECG is critical. An attitude that VF is rare in children can be a self-fulfilling prophecy with a uniformly fatal outcome. The recommended defibrillation dose is 2 J/kg, but the data supporting this recommendation are not optimal and are based on old monophasic defibrillators. In the mid-1970s, authoritative sources recommended starting doses of 60 to 200 J for all children. Because of concerns for myocardial damage and animal data suggesting that shock doses ranging from 0.5 to 1 J/kg were adequate for defibrillation in a variety of species, Gutgesell et al. evaluated the efficacy of their strategy to defibrillate with 2 J/kg monophasic shocks.[257] Seventy-one transthoracic defibrillations in 27 children were evaluated. Shocks within 10 J of 2 J/kg resulted in successful defibrillation (i.e., termination of fibrillation) in 91% of defibrillation attempts. More recent data demonstrate that an initial shock dose of 2 J/kg terminates fibrillation in less than 60% of children, suggesting that a higher dose may be needed.[93,258-260] Interestingly, retrospective observational NRCPR data demonstrate that higher initial doses of 4 J/kg were associated with worse short-term survival (i.e., immediate survival of the cardiac arrest event with a spontaneous rhythm). Despite 5 decades of clinical experience with pediatric defibrillation, the optimal dose remains unknown.

ANTIARRHYTHMIC MEDICATIONS: LIDOCAINE AND AMIODARONE

Administration of antiarrhythmic medications should never delay administration of shocks to a patient with VF. However, after an unsuccessful attempt at electrical defibrillation, medications to increase the effectiveness of defibrillation should be considered. Epinephrine is the current first-line medication for both pediatric and adult patients in VF. If epinephrine and a subsequent repeat attempt to defibrillate are unsuccessful, lidocaine or amiodarone should be considered.

Lidocaine traditionally has been recommended for shock-resistant VF in adults and children. However, only amiodarone improved survival to hospital admission in the setting of shock-resistant VF compared with placebo.[261] In another study of shock-resistant out-of-hospital VF, patients receiving amiodarone had a higher rate of survival to hospital admission than patients receiving lidocaine.[262] Neither study included children. Because there is moderate experience with amiodarone use as an antiarrhythmic agent in children and because of the adult studies, it is rational to use amiodarone similarly in children with shock-resistant VF/VT.

The recommended dosage is 5 mg/kg by rapid IV bolus. There are no published comparisons of antiarrhythmic medications for pediatric refractory VF. Although extrapolation of adult data and electrophysiologic mechanistic information suggest that amiodarone may be preferable for pediatric shock-resistant VF, the optimal choice is not clear.

PEDIATRIC AUTOMATED EXTERNAL DEFIBRILLATORS

Automated external defibrillators (AEDs) have improved adult survival from VF.[263,264] AEDs are recommended for use in children 8 years or older with cardiac arrest.[157,265] The available data suggest that some AEDs can accurately diagnose VF in children of all ages, but many AEDs are limited because the defibrillation pads and energy dosage are geared for adults. Adapters having smaller defibrillation pads that dampen the amount of energy delivered have been developed as attachments to adult AEDs, allowing their use in children. However, it is important that the AED diagnostic algorithm is sensitive and specific for pediatric VF and VT. The diagnostic algorithms from several AED manufacturers have been tested for such sensitivity and specificity and therefore can be reasonably used in younger children.

WHEN SHOULD CARDIOPULMONARY RESUSCITATION BE DISCONTINUED?

Several factors determine the likelihood of survival after cardiac arrest including the mechanism of the arrest (e.g., traumatic, asphyxial, progression from circulatory shock), location (e.g., in-hospital or out-of-hospital), response (i.e., witnessed or unwitnessed, with or without bystander CPR), underlying pathophysiology (i.e. cardiomyopathy, congenital defect, drug toxicity or metabolic derangement), and the potential reversibility of underlying diseases. These factors should all be considered before deciding to terminate resuscitative efforts. Continuation of CPR has been traditionally considered futile beyond 15 minutes of CPR or when more than 2 doses of epinephrine are needed.[266] Presumably in part because of improvements in CPR quality and post-resuscitation care, improved outcomes from in-hospital CPR efforts beyond 15 minutes or 2 doses of epinephrine are increasingly the norm.[83,86] The potential for excellent outcomes despite prolonged CPR has been highlighted by the ECPR data noted above.[267-271] Conversely, the decision to discontinue CPR prematurely is final and cannot be rescinded. In the first decade of the 21st century, there is no simple answer to the important clinical question: when should CPR be discontinued?

Respiratory System

STRUCTURAL AND FUNCTIONAL DEVELOPMENT: AGE-DEPENDENT VARIABLES

Airways and Alveoli

The lungs appear in the fourth to eighth weeks of gestation. At this time, the lung buds divide into the mainstem bronchi; by 6 weeks all subsegmental bronchi are present; and by 16 weeks, the number of airway generations is similar to that of adults. When airway development is complete, the terminal airways remodel and multiply to form a cluster of large saccules, or alveolar precursors, that can support gas exchange. True alveoli appear before and after birth, and the respiratory saccules are thin and septate during postnatal growth.

At birth, children have approximately 24 million alveoli; by 8 years of age, the number has increased to 300 million (Table 79.5). After that, further lung growth is primarily the result of increased alveolar size. There is less elastic tissue in the neonatal lung than in the lungs of adults, and the elastin extends only to the alveolar duct. By 18 years of age, elastin extends to the alveolus and is at its maximum. It then slowly decreases over the next 5 decades. Lung compliance is integrally related to the amount of elastin; hence, compliance peaks in adolescence. It is lower in the very young and the very old. Airways close in the tidal volume range until about 5 years of age.

Pulmonary Circulation

The main axial arteries of the lungs are present at 14 weeks' gestation. By 20 weeks' gestation, the pattern of branching is similar to that of adults, and collateral supernumerary vessels are present. During fetal life, additional arteries develop to accompany the respiratory airways and saccules. Bronchial arteries appear between the 9th and 12th weeks of gestation. The arterial wall develops a fine elastic lamina by 12 weeks' gestation, and muscle cells are present as early as 14 weeks of gestation. By 19 weeks, the elastic tissue extends to the seventh generation of arterial branching, and muscularization extends distally. In the fetus, muscularization of the arteries ends at a more proximal level than in children and adults. The muscularized arteries have thicker walls than arteries of similar size in adults. The pulmonary arteries are actively constricted until the latter part of gestation. In the fetal lamb, pulmonary blood flow is only 3.5% of the combined ventricular output at 0.4 to 0.7 of gestation and is just 7% near term. Immediately after birth, pulmonary blood flow increases to near adult levels. Development of the pulmonary venous system mirrors that of the arterial system. The pulmonary arteries continue to develop after birth; new artery formation follows airway branching up to about 19 months of age, and supernumerary arteries continue to grow until 8 years of age. As alveolar size increases, the acinar branching pattern becomes more extensive and complex. The arterial structure also changes as preexisting arteries increase in size; the thickness of the muscular arteries decreases to adult levels during the first year of life.

Biochemical Development

By 24 weeks of gestation, the alveolar cuboidal epithelium flattens, and type I pneumocytes become the lining and supporting cells for the alveoli. The larger type II cells, which manufacture and store surfactant, also develop at this time. Surfactant initially appears at 23 to 24 weeks' gestation in humans and increases in concentration during the last 10 weeks of gestational life.[68] Surfactant is released into the alveoli at about 36 weeks' gestation, thus making normal extrauterine life possible.

TABLE 79.5 Age-dependent Respiratory Variables: Normal Values

	Newborn	6 months	12 months	3 years	5 years	12 years	Adult
Respiratory rate (breaths/min)	50 ± 10	30 ± 5	24 ± 6	24 ± 6	23 ± 5	18 ± 5	12 ± 3
Tidal volume (mL)	21	45	78	112	270	480	575
Minute ventilation (L/min)	1.05	1.35	1.78	2.46	5.5	6.2	6.4
Alveolar ventilation (mL/min)	385	—	1245	1760	1800	3000	3100
Dead space–tidal volume ratio	0.3	0.3	0.3	0.3	0.3	0.3	0.3
Oxygen consumption (mL/kg/min)	6 ± 1.0	5 ± 0.9	5.2 ± 0.9	—	6.0 ± 1.1	3.3 ± 0.6	3.4 ± 0.6
Vital capacity (mL)	120	—	—	870	1160	3100	4000
Functional residual capacity (mL)	80	—	—	490	680	1970	3000
Total lung capacity (mL)	160	—	—	1100	1500	4000	6000
Closing volume as percentage of vital capacity	—	—	—	—	20	8	4
Number of alveoli (saccules) $\times 10^6$	30	112	129	257	280	—	300
Specific compliance: CL/FRC (mL/cm H_2O/L)	0.04	0.038	—	—	0.06	—	0.05
Specific conductance of small airways (mL/s/cm H_2O/g)	0.02	—	3.1	1.7	0.12	8.2	13.4
Hematocrit	55 ± 7	37 ± 3	35 ± 2.5	40 ± 3	40 ± 2	42 ± 2	43-48
pH_a	7.30 ± 7.40	—	7.35-7.45	—	—	—	7.35-7.45
$Paco_2$ (mm Hg)	30-35	—	30-40	—	—	—	30-40
Pao_2 (mm Hg)	60-90	—	80-100	—	—	—	80-100

Respiratory Transition: Placenta to Lung

By approximately 24 weeks' gestation, the lungs are capable of extrauterine gas exchange. However, several important circulatory and mechanical changes must occur immediately after birth for pulmonary gas exchange to be adequate. Ventilation begins to match perfusion within the first hours of life. Initially, there is right-to-left intrapulmonary shunting through atelectatic areas of the lung, as well as left-to-right shunting through the ductus arteriosus and some right-to-left shunting through the foramen ovale. The resultant PaO_2 of 50 to 70 mm Hg indicates a right-to-left shunt that is three times that of normal adults. Transition from fetal to neonatal respiration and circulation is dynamic. Postnatally, the pulmonary vascular bed remains constricted if it is exposed to acidosis, cold, or hypoxia. If pulmonary artery constriction occurs, right-to-left shunting of desaturated blood through the foramen ovale and ductus arteriosus increases and consequently reduces pulmonary blood flow. Maintenance of this active pulmonary vasoconstriction is called persistent pulmonary hypertension of the newborn or persistent fetal circulation.

Mechanics of Breathing

For ventilation of the lungs, the respiratory muscles must overcome the lung's static-elastic and dynamic-resistive forces. Changes in these opposing forces during postnatal development affect lung volume, the pattern of respiration, and the work of breathing.

Lung Compliance Versus Age

Lung compliance changes with age because of the changing alveolar structure, amount of elastin, and amount of surfactant. At birth, compliance is low because alveolar precursors have thick walls and decreased amounts of elastin. A deficiency of surfactant (e.g., hyaline membrane disease) further decreases lung compliance. The improved lung compliance occurring over the first years of life is the result of continued development of alveoli and elastin.

Chest Wall

The chest wall of infants is very compliant because their ribs are cartilaginous. Because of the box-like configuration of an infant thorax, there is less elastic recoil than there is with the dorsoventrally flattened thoracic cage of adults. Adults have a high proportion of slow-twitch, high-oxidative, fatigue-resistant fibers in their diaphragm and intercostal muscles. Whereas adults have 65% of these fibers in the intercostal muscles and 60% in the diaphragmatic muscles, neonates have only 19% to 46% of these fibers in their intercostal muscles and 10% to 25% in the diaphragm.[70] Consequently, infants are more vulnerable to muscle fatigue and decreased stability of the chest wall. The net effect of the compliant chest wall and the poorly compliant lungs is alveolar collapse and lower resting lung volume (FRC). Despite this tendency for lung collapse, a child maintains a large dynamic FRC via rapid RRs, laryngeal breaking, and stabilization of the chest wall with increased intercostal tone during exhalation.

Upper Airway

The upper airways of children and adults have several anatomic differences that affect their ability to maintain a patent airway. The more anterior and cephalad position of the larynx in children makes the "sniffing position" ideal for mask ventilation and endotracheal intubation. Extreme neck extension can actually obstruct the airway. The narrowest part of the adult airway is the vocal cords. Up to the age of 5 years, the narrowest portion of a child's airway is at the cricoid cartilage, because the posterior larynx is positioned more cephalad than the anterior larynx, which causes the cricoid ring to be an ellipse rather than a circle. By 5 years of age, the posterior larynx has descended to the adult level.[272] An ETT that passes easily through the vocal cords of a young child may cause ischemic damage to the distal airway. The cricoid narrowing and very pliant tracheal cartilage provide an adequate seal around an uncuffed ETT. Children younger than 5 years rarely require a cuffed ETT, although some practitioners use cuffed tubes regularly in these patients.[273]

Closing Capacity

The elastic properties of the lung closely correlate with closing capacity. Closing volume is the lung volume at which the terminal airways close and gas is trapped behind the closed airways. Large closing volumes increase dead space ventilation, which leads to atelectasis and right-to-left shunting of blood. Elastic tissues help keep the airways open, so the greater the elastic stroma in the small airways, the lower the lung volume required to close small, noncartilaginous airways. Closing volume is small in late adolescence and relatively large in the elderly and the very young. Children overcome the complications of large closing volumes and secondary atelectasis by breathing rapidly, by constant activity, and by crying. Closing volume becomes a significant problem in infants who are inactive, sedated, or anesthetized.

Resistive Forces

Neonates have small airways with high resistance or low conductance (conductance = 1/resistance). The diameter of the small airways does not significantly increase until about 5 years of age; hence, young children have elevated airway resistance at baseline and are particularly vulnerable to diseases that cause further narrowing of the airways (i.e., smooth muscle constriction, airway edema/inflammation). The normal high airway resistance of neonates and young children helps maintain FRC.

Control of Breathing

The newborn's respiratory control is unique. Hypoxia initially increases ventilation for a short time. This increase is followed by a sustained decrease in ventilation.[77] The response is more exaggerated in preterm neonates. In full-term infants, it disappears after several weeks. Periodic breathing is also more common in infants, particularly preterm infants, and is probably due to inadequate development of the medullary respiratory centers.

Oxygen Transport: Oxygen Loading and Unloading

Fetal hemoglobin has low levels of 2,3-diphosphoglycerate and an oxygen half-saturation pressure of hemoglobin (P_{50}) of 18 mm Hg, which is much lower than the 27 mm Hg in adults. This lower P_{50} allows the fetus to load more oxygen at low placental oxygen tension, but it makes unloading oxygen in tissues more difficult. Three to 6 months after birth, fetal hemoglobin has been replaced with adult hemoglobin. The increased oxygen content of fetal hemoglobin and the increased fetal hemoglobin concentration are advantageous to the fetus because it allows an oxygen content of 20 mL of oxygen/100 mL of blood to be delivered to the brain and heart. This is the same oxygen content that adults have when breathing room air. The oxygen concentration of neonates at birth is 6 to 8 mL/kg/min. It decreases to 5 to 6 mL/kg/min over the first year of life. The decreased ventilation-perfusion ratio, the decreased P^{63} of fetal hemoglobin, and the progressive anemia characteristic of infants can make it difficult to deliver adequate oxygen during the first few months of life. Infants compensate by having a cardiac output of approximately 250 mL/kg/min for the first 4 to 5 months of life.

RESPIRATORY FAILURE

Respiratory failure is the inability of the lungs to adequately oxygenate and remove CO_2 from pulmonary arterial blood. There are many causes of respiratory failure, including a low environmental oxygen concentration, parenchymal lung disease, and pulmonary vascular disease. A complete history of the severity and chronicity of the respiratory problem helps formulate a differential diagnosis and an approach to treatment. Specific data should include a history of prematurity, previous airway instrumentation, previous mechanical ventilation, nonpulmonary organ dysfunction, and a family history of respiratory disease. A detailed feeding history and up-to-date growth chart may provide valuable information because growth failure may increase the need for oxygen. Usually, 1% to 2% of the total oxygen consumed is used for breathing. During respiratory illnesses, as much as 50% of the total oxygen consumption may be used for breathing. Infants and children with respiratory failure often have intercostal and suprasternal retractions, signs that the work of breathing and oxygen consumption are increased. Patients grunt during expiration in an attempt to maintain FRC. Most infants and children have tachypnea, which also helps maintain FRC by decreasing the time for exhalation. Less energy is required to breath rapidly and shallowly than to take deep breaths. Infants with respiratory failure often have cyanotic lips, skin, and mucous membranes. However, it is often difficult to recognize skin color changes unless the PaO_2 is below 70 mm Hg. Symmetry of chest movement should be noted. Differences in movement may indicate pneumothorax or blockage of a bronchus. The small thoracic volume allows easy transmission of breath sounds from one side to the other. Breath sound may be normal, even when pneumothorax is present. Abdominal distention can dramatically impede breathing in infants and young children.

MONITORING OF RESPIRATORY FUNCTION

An arterial blood gas is considered the gold standard to measure oxygenation, as PaO_2 is measured directly from blood. The percent oxygen saturation of hemoglobin can be measured directly or calculated from PaO_2, pH, $PaCO_2$, and temperature. Venous and capillary blood gases do not predict PaO_2. Use of arterial lines has decreased in pediatric ICUs over time.[274] Pulse oximeters are ubiquitous. Pulse oximeters can provide continuous estimations of SaO_2 when the saturation is less than 97%. This is due to the shape of the oxygen dissociation curve. Pulse oximeters pass at least two wavelengths of light through the patient and the change in the absorbance of light is compared with an algorithm that produces the oxygen saturation. In the saturation range of 91 to 97%, pulse oximeters have been shown to read higher than measured arterial saturations by approximately 1%.[275] However, in the saturation range of 76% to 90%, pulse oximeters read higher than measured arterial saturations by approximately 5% with very wide confidence intervals.[275] Pulse oximeters may also have poorer performance when there is decreased perfusion to the extremity with the sensor. Lastly, most pulse oximeters have difficulty detecting abnormal forms of hemoglobin, such as methemoglobin or carboxyhemoglobin, and will produce erroneous results in their presence.

Umbilical artery cannulation is common in neonates, so those caring for such children can obtain arterial blood and continuously measure arterial blood pressure. These catheters are relatively simple to insert and reasonably easy to maintain.[276-278] The tip of the catheter ideally should be at or just above the level of the aortic bifurcation and below the level of the renal arteries (L2). Once the child's condition is stable, a peripheral artery catheter should be inserted and the umbilical artery catheter should be removed. All intraarterial catheters have the potential to cause distal thromboembolic disease. Care must be taken to flush arterial catheters gently to prevent cerebral or cardiac emboli. With proper insertion and maintenance, serious complications of arterial lines are rare. They have been shown to be relatively safe for short term use.[279] Although arteries that are cannulated for a long time may develop thrombosis in a small study by Ergaz et al. all of the infants that developed thrombosis had spontaneous resolution with sequela.[280]

$PaCO_2$ is used as a measure of ventilation. An arterial blood gas may be the gold standard, $PaCO_2$ obtained from capillary or venous blood gases can provide valuable information. CO_2values obtained from capnography or transcutaneous CO_2(TCOM) can provide continuous information in a manner similar to pulse oximeters.[281] Capnographs produce a waveform displaying exhaled CO_2that can be either time-based or volumetric. Time-based capnography is much more common. Capnographs can either be an aspirating or nonaspirating system. An aspirating system takes gas from the ventilator circuit and measure the CO_2. A nonaspirating system has an exhalation chamber placed in line with the ventilator circuit. The system uses an infrared light source and detector which measures the exhaled CO_2. There is a great amount of information that can come from capnography, including the end-tidal CO_2($ETCO_2$) value, RR, dead space calculations, cardiac output, and detection of obstruction of the airways.

For time-based capnography, the plateau of the slope will always be lower than $PaCO_2$. Elevations in $ETCO_2$ must be investigated as they signal a change in ventilation. For individuals with healthy lungs, this $ETCO_2$ to $PaCO_2$ gradient is usually 2 to 5 mm Hg. The gradient increases with increased dead space, abnormalities in the pulmonary vasculature, decreased cardiac output, and pulmonary over distension. $ETCO_2$ from capnography can be used clinically to calculate the approximate alveolar dead space by the alveolar dead space fraction (AVDSf). $AVDSf = (PaCO_2 - PETCO_2)/PaCO_2$. AVDSf is a reasonable indicator of alveolar dead space[282] and has been shown in several pediatric patients with acute hypoxemic respiratory failure to be associated with mortality.[283-285] Other valuable information is available from the waveform produced by time-based capnography. As an example, a rising upslope to the exhalation phase can indicate obstructive airways disease. Time-based capnography is more accurate with slower RRs and when there is a minimal leak around the ETT.

Volumetric capnography traces the CO_2 concentration against the exhaled volume and is appearing as a feature on some ventilators. Free-standing monitors that provide the same measure are also available. Volumetric capnography provides direct information for dead space calculations. Clinically volumetric capnography is helpful in setting the optimal PEEP. In this way, PEEP can be titrated to balance improved oxygenation through alveolar recruitment and decreased dead space by not causing overdistension. Volumetric capnography can also be used to demonstrate a response to bronchodilator therapy.

In circumstances such as high frequency ventilation (HFV), the use of transcutaneous CO_2monitoring (TCOM) provides a continuous measure of ventilation. The TCOM module heats the skin underneath a small sensor. There is increased diffusion of CO_2across the skin as the capillary bed dilates from the heat. The diffused $CO_2$is then measured. When the TCOM is first set up, it should be calibrated against a capillary or arterial blood gas. There can be drift of calibration over time, but newer modules have improved stability. A recent study by Bhalla et al. demonstrated that transcutaneous CO_2monitoring provides an acceptable estimate of $PaCO_2$, even with low cardiac output or increased subcutaneous tissue.[281] In their study, it did not perform well in patients with cyanotic heart disease.

The effort of breathing with or without a ventilator can be obtained by the objective measurement value of the pressure-rate-product (PRP). The pressure measure by a balloon-tipped catheter placed into the distal third of the esophagus can be used as a surrogate for pleural pressure. The PRP is the change in esophageal pressure (Pes) multiplied by the RR. PRP = Pes × RR. The PRP has been used as an objective measure of effort of breathing in studies: before and after extubation,[286,287] with PEEP and obstructed airways disease,[277] evaluating increasing inspiratory load;[278] pressure-rate product and phase angle as measures of acute inspiratory upper airway obstruction in rhesus monkeys, evaluating effectiveness of high-flow nasal cannula;[288,289] and evaluating effectiveness of noninvasive ventilation (NIV) in infants.[290] Some ventilators can measure esophageal pressure, or it can be obtained with separate devices. We have found that the accuracy of PRP measurements is sensitive to the volume of air used to fill the esophageal catheter.[291] In addition to measuring the PRP, the esophageal pressure is very important in measuring the pressure across the lungs or the transpulmonary pressures. Many adult studies are appearing demonstrating the benefits of titrating ventilator settings to trans-pulmonary pressure for patients with acute respiratory distress syndrome (ARDS).[292-294] The transpulmonary pressure may have particular benefit in patients who are obese and requiring mechanical ventilation for respiratory failure,[295-298] where the decreased compliance of the chest wall may cause practitioners to limit ventilator pressures. For adult medicine, the field of esophageal pressure monitoring and the titration of mechanical ventilation to transpulmonary pressure has recently grown significantly. The need for and goals of this type of monitoring can be best summarized in a few review articles,[299,300] including one from the PleUral pressure working Group (PLUG-Acute Respiratory Failure section of the European Society of Intensive Care Medicine).[301]

The phase of breathing or the synchrony between movement of the abdomen and the chest wall can be measured with respiratory inductance plethysmography (RIP).[302] This noninvasive measure uses elastic bands placed around the abdomen and chest. Movement of the abdomen and chest changes the inductance of a small wire in the bands. Movement of the abdomen relative to the chest can be presented graphically or measured as the phase angle. When there is obstruction to breathing, such as with upper airway obstruction, there is a lag in the movement of the abdomen and chest wall, which is identified as an increasing phase angle. The phase angle obtained by RIP is an objective measure of the degree of upper airway obstruction[278,302,303] and can be used to evaluate the effectiveness of therapy.[304-306] This is a valuable tool for research in the area of causes and treatment of upper airway obstruction, as there is great interobserver variability in the clinician's assessment of this process.[307] RIP can easily be measured with free-standing devices and may have an increased role in future pediatric studies.

A great deal of information on the respiratory effort of patients receiving mechanical ventilation can be obtained from respiratory spirometry. Spirometry can display flow-volume loops, pressure-volume loops, in addition to graphs of flow-time, pressure-time, and volume-time. The characteristic shape of some respiratory flow-volume loops can help with the diagnosis of various respiratory diseases. There is a classic scooped out appearance to the exhalation portion of a flow-volume curve with obstructive lung disease. The pressure-volume loops obtained on the ventilator can be used to increase PEEP to keep lung tissue recruited above an area of potential atelectasis. This can be seen graphically as a lower inflection point on the inspiratory curve. This is where the curve moves from a flat area to an area of maximal compliance where there is the greatest change in volume for a given change in pressure. There is also an upper inflection point on pressure volume loops where overdistension of the lungs can be identified if the inspiratory pressure or volume is too great. The pressure-volume curve with over-distension looks like a bird's beak and ventilator settings should be reduced.

There are multiple noninvasive techniques that can provide additional information on the patient's respiratory status. Radiologic evaluation of the nasopharynx, neck, and thorax can provide meaningful information regarding the cause and severity of the respiratory dysfunction. Fluoroscopy can be used to evaluate the airways and movement of the diaphragm in an uncooperative child. Electrical impedance tomography (EIT) is a noninvasive technique that does not use ionizing radiation that can provide information on regional lung ventilation. The technique uses electrodes placed on the chest wall to measure the electrical conductivity and impedance of the lung to form a tomographic image. The images are used to determine which areas of the lungs have atelectasis, normal ventilation, or overdistension. At the moment, there is much more adult data showing uses of and management strategies with EIT,[308-311] as compared with pediatrics.[312-314] However, as more companies produce the machines and more adult manuscripts are published, we expect there will be an increased use of EIT in pediatric mechanical ventilation monitoring. Finally, there is a rapid growth of point of care ultrasound use in pediatrics. This has multiple benefits for the patient, as it can be provided at the bedside and does not use ionizing radiation. Lung ultrasound offers the ability to identify pneumothorax, alveolar consolidation, pneumonia, atelectasis, pulmonary edema, pleural effusions, and diaphragm movements and thickness. There are an increasing number of pediatric manuscripts identifying the benefits of lung ultrasound.[315-318] In the near future, ultrasound diaphragm thickness and how it changes over time may be used to guide mechanical ventilation strategies and help predict extubation success.[319-322]

RESPIRATORY FAILURE

The cause of respiratory failure depends to some degree on the age of the patient. Newborn respiratory failure is often the result of congenital anomalies and immaturity of the lungs and their blood vessels. Congenital anomalies can include airway malformations, dysgenesis or malfunction of the lung or nonpulmonary organs, and abnormalities of the pulmonary vessels. Lesions of immaturity include apnea of prematurity, hyaline membrane disease, and abnormalities of surfactant production and secretion. During the perinatal period, neonates are subject to infections and stress. Persistent pulmonary hypertension can complicate neonatal pulmonary and nonpulmonary problems. These and other important causes of respiratory failure in the newborn are listed in Table 79.6. A wide variety of disorders cause respiratory failure in older children (Box 79.3). Regardless of the specific cause, respiratory failure can be categorized as hypoventilation syndromes in patients with normal lungs, intrinsic alveolar and interstitial disease, and obstructive airway disease.

HYPOVENTILATION SYNDROMES IN CHILDREN WITH NORMAL LUNGS

Causes of hypoventilation include neuromuscular disease, central hypoventilation, and structural/anatomic impairment of lung expansion (i.e., upper airway obstruction,

TABLE 79.6 Causes of Neonatal Respiratory Distress

Location	Congenital Abnormalities	Developmental Immaturity	Specific Neonatal Stress
Impaired control of ventilation	Central nervous system dysgenesis Ondine's curse	Apnea of prematurity Intracranial hemorrhage	Drug intoxication (note maternal drugs) Sepsis Central nervous system infection Seizures
Neuromuscular disorders	Congenital myopathies		High cervical cord injuries
Structural impairment	Thoracic deformities Lung hypoplasia Diaphragmatic hernia Potter syndrome Abdominal malfunction Gastroschisis Omphalocele		Severe abdominal distention Pneumothorax or other leak
Airway obstruction	Choanal atresia		Massive meconium aspiration
Upper airway	Pierre Robin syndrome Laryngeal web/cleft Congenital tracheal/laryngeal stenosis Recurrent laryngeal palsy Hemangioma Lymphangioma		Vocal cord paralysis is secondary to myelodysplasia
Lower airway	Tracheoesophageal fistula Lobar emphysema		Meconium/blood aspiration
Alveolar disorders		Respiratory distress syndrome	Bronchopulmonary dysplasia

massive abdominal distention). These clinical conditions are characterized by inadequate lung expansion, secondary atelectasis, intrapulmonary right-to-left shunting, and systemic hypoxia. Atelectasis and the secondary reduction in FRC increase the work of breathing. The child's response to the increased work of breathing and lower lung volumes is to breathe faster with a smaller tidal volume. This pattern of breathing eventually increases the amount of atelectasis and shunting. As a result, children with intrinsically normal lungs and hypoventilation syndromes exhibit tachypnea, small tidal volumes, increased work of breathing, and cyanosis. Chest radiographs reveal small lung volumes and miliary or lobar atelectasis. Positive-pressure ventilation and PEEP quickly reverse the pathologic processes.

Primary Pulmonary Alveolar or Interstitial Disorders

Intrinsic lung disease involving the alveoli or pulmonary interstitium decreases lung compliance and increases airway closure, both of which cause atelectasis and increase the work of breathing. Edema or inflammation of the alveoli or fibrosis of the interstitium decreases lung compliance. The stiffer lung requires a greater negative intrapleural pressure for air movement, thereby increasing the work of breathing and the risk for pneumothorax.

Obstructive Airway Disease

Airway obstruction can be extrinsic or intrinsic. Intrinsic small airway obstruction commonly occurs with bronchiolitis, bronchopneumonia, asthma, and bronchopulmonary dysplasia (BPD). Airway obstruction decreases conductance and increases airway resistance and the work of breathing. Partial obstruction impedes expiration more than inspiration and causes gas trapping or regional emphysema. Complete airway obstruction results in atelectasis and right-to-left shunting of blood within the lung. Patients with disease of the small airways usually have a mixture of total and partial airway obstruction and inhomogeneous collapse and overdistention of the lung. The areas of collapse cause intrapulmonary right-to-left shunting of blood, and the overdistended areas increase the amount of dead space. If the entire lung is overdistended, compliance is decreased and the work of breathing is increased. The clinical and radiographic picture varies with the different degrees of collapse and overdistention of the lung. In summary, all causes of respiratory failure share similar pathophysiology: atelectasis and decreased FRC with intrapulmonary right-to-left shunting of blood or alveolar overdistention with increased dead space and decreased CO_2 elimination, or both. The increased work of breathing associated with all forms of respiratory dysfunction can cause fatigue and a breathing pattern that further complicates the initial process. It may also lead to apnea, hypoxia, and cardiac arrest in young children if the increased work of breathing is not quickly detected and treated.

RESPIRATORY CARE

A patient's FiO_2 can be increased by a number of means including nasal cannula or mask. The FiO_2 can be increased up to approximately 40% with nasal cannula oxygen at 5 L flow/min. However, this high rate of flow can become uncomfortable. As room air is entrained around the cannula during inspiration the FiO_2 cannot be increased further with nasal cannula. It should be noted that the size of the patient correlates with the inspiratory volume with each breath. The larger the patient, the greater inspiratory volume is relative to flow from the cannula and the greater volume of room air that is entrained. In turn, the smaller a patient the less room air is entrained and there may be a greater impact on FiO_2.

BOX 79.3 Causes of Respiratory Failure in Children

1. Impaired control of ventilation
    - Head trauma
    - Intracranial hemorrhage
    - Increase intracranial pressure secondary to tumor, edema, hydrocephalus, Reye syndrome
    - Central nervous system infections
    - Drug intoxication
    - Status epilepticus
2. Neuromuscular disorders
    - High cervical cord injury
    - Poliomyelitis
    - Guillain-Barré syndrome
    - Neurodegenerative disease (e.g., Werdnig-Hoffman syndrome)
    - Muscular dystrophies and myopathies
    - Myasthenia gravis
    - Botulism
    - Tetanus
    - Phrenic nerve injury
3. Structural impairment
    - Severe kyphoscoliosis
    - Flail chest
    - Large intrathoracic tumor
    - Pneumothorax or pneumomediastinum
    - Large pleural effusion, hemothorax, empyema
    - Severe abdominal distention
    - Severe obesity (pickwickian syndrome)
4. Airway obstruction
    - Upper airway
    - Congenital anomalies
    - Tumor, intrinsic or extrinsic
    - Epiglottitis
    - Croup (laryngotracheobronchitis)
    - Foreign body
    - Postintubation edema, granulation tissue, or scarring
    - Vocal cord paralysis
    - Burns
    - Vascular ring
    - Lower airway
    - Asthma
    - Bronchiolitis
    - Foreign body
    - Lobar emphysema
    - Cystic fibrosis
5. Alveolar disorders, pneumonia
    - Infectious: bacteria, virus, fungus, *Pneumocystis* species
    - Chemical: aspiration, hydrocarbon, smoke inhalation
    - Pulmonary edema: cardiogenic, near-drowning, capillary leak syndrome
6. Massive atelectasis
7. Oxygen toxicity
8. Pulmonary confusion
9. Pulmonary hemorrhage

The FiO_2 can be increased further with a properly fitted face mask. The open holes of a venture or simple face mask allow for greater entrainment of room air as compared with a non-rebreather face mask that has no holes. A FiO_2 approaching 1.0 can be obtained with a non-rebreather face mask with an oxygen reservoir and one-way valve. Patients with respiratory distress while on the pediatric ward may temporarily require a non-rebreather mask at high flows. If there is no significant improvement to immediate interventions, arrangements should be made to transfer the patient to the PICU. Non-rebreathing mask systems can be humidified for comfort, but they don't provide any positive pressure to the airways.

High flow humidified nasal cannula (HFHNC) oxygen can provide a higher FiO_2 and is more easily tolerated as compared with standard nasal cannula. The gas in HFHNC is heated to body temperature and near completely humidified with water vapor. HFHNC can be delivered with flow rates in pediatrics up to 2 L/kg/min. HFHNC has been shown in a number of studies to decrease the effort of breathing in critically ill children.[323-325] HFHNC has been used frequently to support patients with bronchiolitis.[324-328] Weiler et al. demonstrated that the lowest effort of breathing for toddlers with bronchiolitis was at greater than 1.5 L/kg/min of flow.[324] It is unclear whether the significant benefits of HFHNC come from washing out carbon dioxide from the airways,[329,330] from the generation of positive pressure,[331] or from increases in end expiratory lung volumes.[332] The potential for complications exists with higher gas flow rates. Air leak syndrome was reported in three patients by Hegde et al.[333] As the use of HFHNC increases, other problems may be identified. Given that the amount of FiO_2 delivered approaches 1.0, HFHNC outside of an ED or ICU setting should be used with caution. The high degree of respiratory support provided can mask a significant degree of respiratory distress. However, with appropriate monitoring and protocols, it is possible to provide HFHNC on a general ward to specific populations such as stable patients with bronchiolitis. Franklin et al.[326] recently published a study of children younger than 12 months of age with bronchiolitis. The use of HFHNC significantly reduced the risk of escalation of care (12%) as compared with regular nasal cannula (23%).

NIV can be supplied with continuous positive airway pressure (CPAP) or bilevel positive airway pressure (BiPAP). This is typically delivered with a tight fitting nasal or face mask that allows for the development of positive airway pressure. Most modern ventilators can be set to deliver this therapy, but specific free-standing BiPAP machines are more often used. BiPAP therapy is best for short-term use and in patients who have the ability to cough and protect their airway. It is not an absolute that the patient initiates every breath as a back-up rate can be set. However, if the patient is completely reliant on the rate set on the machine, intubation should be considered. Other indications for conversion from BiPAP to endotracheal intubation include pressure related tissue breakdown on the face from constantly wearing the mask and the need to initiate enteral feedings, as patients are typically NPO on BiPAP, increasing pressure settings on the BiPAP machine.

CPAP reduces the patient's work of breathing by providing airway pressure, reducing atelectasis, decreasing dead space, and improving the balance of ventilation to perfusion. An initial CPAP pressure is typically 4 to 6 mm Hg and is then increased as needed and as the patient tolerates the therapy. Given that the feeling of positive airway pressure is a bit foreign, starting with lower pressures and increasing gives the patient a chance to adapt. We typically start patients on CPAP therapy for several minutes even if they will ultimately receive BiPAP. For BiPAP, the expiratory pressure is also initially at 4 to 6 mm Hg and the inspiratory pressure is set at 4 to 6 mm Hg above that. The inspiratory and expiratory pressures are adjusted, as well as the rise time to inspiratory flow. All of these changes can help the patients tolerate therapy. Given the tight seal, a FiO_2 of 1.0 can be delivered. With use of the full face mask, patients are at risk for aspiration if they vomit. BiPAP therapy is being used in status asthmaticus,[334,335] and it may provide a more effective means of delivering aerosolized medication. The use of BiPAP therapy for this indication may increase over time as it is being recommended in current guidelines.[336,337] BiPAP can also be used as an ongoing therapy for chronic respiratory failure for such things as central hypoventilation or restrictive lung disease. These patients may be able to receive their therapy at home and are typically followed by the hospital's pulmonary service.

The size of ETT required should be selected carefully. One formula that estimates the appropriately sized tube for children older than 2 years is (age + 16)/4. This formula provides the internal diameter of the appropriately sized ETT. The correct size should have a slight air leak when a positive pressure of 20 to 30 cm H_2O is applied. Serious lifelong laryngeal and subglottic damage can result from using inappropriately large ETTs, particularly in children with inflammatory lesions of the upper airway such as laryngotracheobronchitis. Because of the more flexible tracheal cartilage and the relative subglottic narrowing of children, uncuffed ETTs generally provide an adequate seal in those younger than 5 years. However, if the patient has lung disease that requires high ventilation pressure, a cuffed tube is more appropriate. Small cuffed ETTs are frequently used in the ICU in younger patients,[338] but care should be taken to ensure that there is a small leak of air at 25 to 30 cm H_2O. Cuffed tubes will usually eliminate the air leak around an ETT, but overinflation of the cuff may occlude venous flow and injure the airway. There are presently no data on the long-term safety of using cuffed ETTs in young children. However, there has been work by Khemani et al.[339] that showed risk factors associated with the development of postextubation subglottic upper airway obstruction included low cuff leak volume or high preextubation leak pressure. We should take care to make sure that ETT cuffs are appropriately inflated.

With endotracheal intubation, it is important to correctly position the ETT. If correctly positioned, chest movements should be symmetric, and breath sounds should be equal when auscultated in the axillae. An electronic or colorimetric CO_2detection system helps confirm whether the ETT is in the trachea or the esophagus.[340] If the double lines on the ETT are at the level of the vocal cords, the ETT is usually in the correct position. Another way to correctly position the ETT is to advance it into the right mainstem bronchus and listen for breath sounds in the left axilla. Breath sounds will be diminished. Withdraw the ETT slowly. When breath sounds are heard on the left, pull the tube out an additional 1 to 2 cm, depending on the size of the child. If the breath sounds are equal, fix the tube in place. The tip of the ETT should be midway between the vocal cords and the carina on the chest radiograph. In small infants, the distance between the carina and the vocal cords is very short. It is easy to inadvertently place the ETT in the right mainstem bronchus in small infants because of this short distance. Flexion of the head moves the ETT into the airway. Extension moves it toward the vocal cords. Turning the head to the side may obstruct the tip of the ETT if it comes in contact with the tracheal wall, which may cause CO_2retention or hypoxemia, or both (unpublished data). It is common to leave a child's trachea intubated for 2 weeks or longer before performing a tracheostomy. This is possible with proper humidification of the inspired gases, improved endotracheal suctioning and monitoring (SaO_2), and excellent nursing care. Everyone caring for the child must be constantly alert to the possibility that the ETT will become obstructed by secretions or that accidental extubation or mainstem bronchus intubation will occur. Tracheostomy is indicated when children require a long-term artificial airway for mechanical ventilation, for endotracheal suctioning, or to bypass an upper airway obstruction. Accidental dislodgement of the tracheostomy tube before the tract is well healed can be life threatening. Reinsertion of a tracheostomy tube during the first 72 hours after insertion can be very difficult and can create false passages that can make it impossible to ventilate the lungs or can cause pneumothorax.

Intubation and mechanical ventilation can provide significant elevations in airway pressure as compared with NIV and a FiO_2 of 1.0. There can be regional variation to the mode of mechanical ventilation chosen, but there is likely a greater use of pressure controlled ventilation rather than volume controlled ventilation in pediatric ICUs. However, as there are no studies looking at outcomes with mode of ventilation, we cannot recommend one mode over another. With pressure-controlled ventilation, pressure is set and the tidal volume may change as the pulmonary compliance changes. With volume-controlled ventilation, tidal volume is set, and the pressure needed to deliver that may change as the pulmonary compliance changes. These are likely the two main modes of mechanical ventilation in pediatric ICUs. For the majority of intubated children who have reasonable pulmonary compliance, there are little differences between the two modes. One potential advantage of pressure-controlled ventilation for patients who are sicker with poorer pulmonary compliance is that most ventilators in this mode use a decelerating inspiratory flow pattern. This means that the flow of gas is greatest early in inspiration and then decelerates to zero flow when the peak pressure is achieved. This can result in the delivery of a larger tidal volume for a lower peak pressure as compared with the same pressure that might be required in a tidal volume mode.

There are additional modes available on modern ventilators that may have benefit for patients with lung injury. The names of the modes will differ between the ventilator manufacturers. Many will have a mode where a desired tidal volume is guaranteed and the lowest pressure necessary to achieve that is used. Terms usually given to define this mode are *pressure-regulated volume control* and *volume guarantee*. These modes may reduce the pressure used, but they work best when the patient is well sedated and not competing with the ventilator.

Neurally adjusted ventilatory assist is a newer method of triggering ventilator synchrony available on the Servo-i ventilators by Maquet. This uses a small esophageal probe that can sense the electrical activity of the diaphragm and use that activity to synchronize the ventilator. The potential benefits of improved triggering such as improved comfort, lower ventilator settings, and increased minute ventilation have been shown in some studies.[341,342] Some degree of expertise is necessary with the mode, as the electrical activity of the heart can also cause auto-triggering of the ventilator.[343]

Airway pressure release ventilation (APRV) is a mode of mechanical ventilation that is less common than pressure control or volume control. There is adult data that was recently published by Zhou et al.[344] that early use of APRV can reduce length of mechanical ventilation. As we do know, however, children are just little adults. Lalgudi et al.[345] recently published the results of a randomized controlled trial of APRV in children with ARDS. The trial was stopped early for increased mortality in the APRV arm. There are few published pediatric studies using this mode,[346-349] and its benefits and limitations continue to be explored. Like other modes of ventilation, its use appears to be regional, and some will only consider this as rescue therapy when patients fail conventional ventilation.

To describe its use, APRV is essentially CPAP with brief, intermittent release coupled with spontaneous ventilation. The high CPAP level (Phigh) maintains alveolar recruitment and aids in oxygenation over a period of time (Thigh), and the timed release to a low pressure (Plow) minimizes resistance to expiratory flow and carbon dioxide removal. In addition, the patient is able to spontaneous breath during all phases, Phigh and Plow, potentially allowing for improved pulmonary mechanics and gas exchange. APRV differs from other modes of ventilation because it relies on an intermittent decrease in airway pressure, instead of an increase in airway pressure to maintain an open lung strategy for ventilation. Therefore, the release time (Tlow) should be set long enough to allow for an adequate tidal volume (6-8 mL/kg), but short enough to avoid alveolar collapse and atelectrauma. In summary, the operator-controlled parameters in APRV are: Phigh, Thigh, Plow, Tlow, and FiO_2. Recommendations for implementing APRV are limited in pediatrics, and thus extrapolated from adult recommendations.[350] Plow is initially set a zero. Phigh can be set by several methods such plateau pressures or 75% of peak inspiratory pressure; however, when transitioning from conventional modes of ventilation, Phigh is often determined by mP_{AW} pressure formula where the mP_{AW} is set 2 to 3 cm H_2O above conventional mP_{AW}: (Phigh × Thigh) + (Plow × Tlow) / (Thigh + Tlow). To determine Thigh and Tlow, first determine the total cycle time according to a normal RR range for the patient's age (i.e., a RR of 20 yields a total cycle time of 3 seconds). Thigh will be the total cycle time minus a Tlow of 0.2 to 0.6 seconds, initially starting at 0.4 seconds (i.e., total cycle time of 3 seconds yields a Thigh of 2.6 seconds and Tlow of 0.4 seconds), or Number of cycles (RR) = 60 seconds/(Thigh + Tlow). Transitioning to APRV, like transitioning to HFOV, will take time for optimal lung recruitment. After several hours, if the patient continues to have severe hypoxemia, Thigh can be increased to aid in oxygenation. Once established Plow and Tlow usually do not require further changes; however, as lung compliance improves, Phigh and Thigh can be decreased and increased, respectively, to wean a patient toward a target of a continual CPAP of 5 to 6 cm H_2O in preparation for extubation. APRV may be advantageous to other modes of advanced mechanical ventilation because of the patient's ability to breathe spontaneously throughout the entire ventilatory cycle improving respiratory mechanics and reducing the need for sedation and neuromuscular blockade. However, some authors are concerned that there may be a higher incidence of cyclic alveolar collapse during airway release leading to a greater degree of atelectrauma, as compared with HFOV.[346,347]

High frequency oscillatory ventilation (HFOV) is being used in pediatrics as a rescue therapy for acute lung injury (ALI) or ARDS. HFOV is a subset of HFV. Use of HFOV was first described by Lunkenheimer in 1972.[351] A 1994 publication by Arnold et al.[352] is the only multicenter randomized trial of HFOV. This study showed lower use of oxygen supplementation in the HFOV group at 30 days. There have been other pediatric studies showing positive benefit of HFOV such as a single center prospective study by Samransamruajkit et al.[353] and a single center retrospective study by Babbitt et al.[354] The conclusion that could be drawn by many studies with HFOV in pediatrics is that for disease processes with significant mortality, rescue therapy with HFOV may be appropriate and may show improved outcomes. In some of the most critically ill patients with a very high mortality such as immune compromised children with ARDS, the response to HFOV has been used as diagnostic criteria to identify survivors from nonsurvivors.[347,355] Early use of HFOV has been shown to decrease mortality in patients who have undergone hematopoietic cell transplant who have developed severe pediatric ARDS.[356] There is some adult data using HFOV from large randomized trials. The OSCAR trial[357] was a negative study and the OSCILLATE Trial[357] was stopped early for a potential increase mortality in the HFOV group. It is unclear whether these findings can be translated to pediatric patients. The disease processes and the condition of our patients can be very different as compared with adults. Bateman et al.[358] used a propensity score model to reanalyze results from the Randomized Evaluation of Sedation Titration for Respiratory Failure (RESTORE) Study.[359] Using their adjusted models, they found that early use of HFOV was associated with longer mechanical ventilation. There also was no mortality benefit to the use of HFOV. Given the results of the adult studies as well as those from Bateman et al.,[358] it is unclear if the motivation would be present to perform a multicenter HFOV trial in pediatrics. There may continue to be other indications for HFOV in pediatrics, such as air leak syndrome or congenital diaphragmatic hernia.

To describe its use, HFV is a type of mechanical ventilation where the RR of the ventilator is much greater than a normal physiologic rate. Maintaining the same minute ventilation these ventilation modes produce tidal volumes that are very small. There are several different methods, but most commonly used in pediatrics is the HFOV. This type of ventilator houses a piston that is attached to semi-rigid connecting tubing which attaches to the ETT. This circuit can be pressurized to a set mean airway pressure (MAP). The piston then oscillates up to 840 times a minute, creating small positive and negative respiratory cycles. The MAP is higher as compared with conventional ventilation, and this prevents atelectasis as well as shear forces from opening and closing alveoli with each respiratory cycle. The FiO_2 is set as in a conventional ventilator. The frequency of oscillation of the piston is adjusted to remove carbon dioxide and can vary between 6 and 14 Hz (Hz = 60 cycles/s). The amplitude of the ventilator is the distance the piston moves with each excursion, and by these excursions small breaths are propelled down the tubing. Several proposed mechanisms for the method of gas transport during HFOV have been proposed but none have been proven. Tidal volumes are dependent on the patient's compliance, ETT size, device frequency, and device amplitude. Tidal volume is inversely related to cyclic frequency: VCO_2 = frequency × VT_2. Transitioning from conventional modes of ventilation to HFOV, the initial power setting (ΔP/amplitude) is adjusted to visible chest "wiggle" from the clavicles to the abdomen or pelvis. MAP (mP_{AW}) is initially set approximately 5 cm H_2O greater than the last mP_{AW} on conventional ventilation, just prior to the initiation of HFOV. Traditionally, tidal volumes in HFOV are considered to be just above FRC; however, it is difficult to measure actual tidal volumes and provide precise "optimal" lung volumes strategy. Clinically, MAP mP_{AW} is titrated by upward by 1 to 2 cm H_2O till oxygenation improves, and inspired oxygen concentrations can be weaned to less toxic levels, below 0.60. While titrating mP_{AW}, it is important to assess for overdistention by following chest radiographs (CXR): overdistention/hyperinflation is determined by greater than nine posterior ribs or flattened hemi-diaphragms on CXR. Initial frequency settings, measured in Hz, can be found in Table 79.7. HFOV is the only mode of ventilation with active expiration. If hypercarbia, despite allowances for permissible hypercapnia, leads to profound respiratory acidosis and patient instability, minute ventilation can be improved by several means during HFOV. First, one of the drawbacks of HFOV is the lack of spontaneous ventilation and adequate airway clearance; therefore, inline suction (without breaking into the circuit causing derecruitment) should be used to ensure adequate airway, ETT patency, and lung recruitment. Second, ΔP should be increased to maximize lung recruitment and increase minute ventilation. Third, frequency (Hz) can be slowly decreased to enhance lung recruitment and increase minute ventilation. Finally, the ETT cuff should be deflated to allow additional escape of CO_2around the ETT. Disadvantages of HFOV include no partial ventilatory support leading to increased requirements for sedation and paralysis, cardiopulmonary interactions due higher mP_{AW} and decreased venous return, and loss of alveolar recruitment if circuit detached for suctioning of manual ventilation.

High frequency percussive ventilation (HFPV) pneumatically stacks subtidal volume breaths at a set rapid rate superimposed upon conventional cyclic rates. This allows for a progressive stepwise inflation of the lung to a set peak pressure while allowing for passive exhalation to a preset lower pressure. HFPV has been well-described in the inhalational injury population for its ability to safely oxygenate and ventilate with continuous pneumatically-powered high frequency percussions to facilitate clearance of airway debris.[360-362] These properties may be particularly useful in pediatric patients with acute respiratory failure, by improving oxygenation and ventilation while maintaining lung protective strategies.[363]

TABLE 79.7 Initial Frequency Settings in High-Frequency Oscillatory Ventilation

Patient Weight (kg)	Initial Frequency Setting (Hz)
<2	15
2-15	10
16-20	8

PEDIATRIC ACUTE RESPIRATORY DISTRESS SYNDROME

ARDS is a severe form of ALI that can result from a number of triggers that directly or indirectly injure the lung. The disease results in inflammation of the lungs, edema of the alveoli, and hypoxemic respiratory failure. Prior definitions of pediatric ARDS (PARDS) often were adapted from studies on adult patients and adult consensus conferences. Although PARDS represents a small portion of PICU admissions, it is very clinically important as it carries a very high mortality rate. In turn, PARDS garners a significant amount of attention from PICU researchers and clinicians. Since 2012, PICU intensivists had been using the *Berlin definition* of ARDS[364,365] for management and study enrollment. Finally, in 2015 pediatrics had its own unique definition of ARDS. In 2015 the Pediatric Acute Lung Injury Consensus Conference (PALICC) completed their 2-year process of consensus meetings to provide a new definition of PARDS and guidelines for management.[366] The PALICC group included 27 experts from 8 countries. They used peer reviewed data that was specific to pediatrics to form new guidelines. Where data were unavailable specifically for pediatrics, recommendations were adapted from adult or neonatal data as appropriate. In areas where there was no available data, expert opinion formed the basis of their recommendations. Multiple follow-up publications have provided important information in PARDS, including methodology of the group,[367] the incidence and epidemiology,[368] comorbidities,[369] means of ventilator support,[370] noninvasive support,[371] monitoring,[372] use of ECMO,[373] and outcomes.[374] The group identifies the need for future randomized control trials in PARDS.

There are several key aspects to defining PARDS.[375] The PALICC definition of PARDS excludes neonates with perinatal-related lung disease, as it is likely a different entity. The lung injury should occur within 7 days of a known clinical insult. The hypoxemic respiratory failure should not be able to be explained by cardiac failure or fluid overload. Chest radiographs typically have new infiltrates consistent with parenchymal lung disease. There are now separate sections for the use of noninvasive and invasive mechanical ventilation. One significant difference in comparison to adult ARDS definitions is that the definition of PARDS for mechanically ventilated patients includes stratification by oxygenation index or oxygen saturation index. Oxygenation index (OI) = $[FiO_2 \times MAP \times 100]/PaO_2$. The oxygen saturation index (OSI) = $[FiO_2 \times MAP \times 100]/S_pO_2$. Mild PARDS is $4 \leq I < 8$, as well as $5 \leq OSI < 7.5$. Moderate PARDS is $8 \leq OI < 16$, as well as $7.5 \leq OSI < 12.3$. Severe PARDS is $OI \geq 16$, as well as $OSI \geq 12.3$. There is additional information for patients with cyanotic heart disease, chronic lung disease, and left ventricular dysfunction. Future studies will need to address these more difficult aspects of defining PARDS.

The management of mechanical ventilation in PARDS currently can be summarized as the use of restrictive tidal volumes, increased use of PEEP, an ongoing relative tolerance of hypoxemia as long as it does not alter systemic oxygen delivery, and a tolerance of relative hypercarbia to reduce trauma from elevated mechanic ventilator pressures. The PALICC group among many others recognizes that there has never been a randomized control trial of tidal volume restriction in PARDS. There are also prior studies that have demonstrated a lower mortality with larger tidal volumes in pediatric patients.[376,377] This seems to be a result of the increased use of pressure control ventilation in pediatric patients. An individual patient might be sick enough to be classified as having ARDS, but those with a milder form of the disease have better pulmonary compliance. As pressure is set on the ventilator, larger tidal volumes occur with better compliance. The PALICC guidelines do not make a recommendation as the mode of ventilation. However, the guidelines do recommend targeting the delivered tidal volume to be "in or below the range of physiologic tidal volumes for age/body weight (i.e., 5-8 mL/kg predicted body weight) according to lung pathology and respiratory system compliance."[366] It should be noted that PALICC guidelines do recommend adjusting the tidal volumes to the degree of disease severity. They recommend tidal volumes of 3 to 6 mL/kg predicted body weight for those patients with poor respiratory system compliance. They do believe the larger tidal volumes could be appropriate for patients with better pulmonary compliance.

Potentially, one of the more important recommendations from the PALICC group has been the increased application of PEEP. They recommended levels of PEEP of 10 to 15 cm H_2O for patients with severe PARDS and identify that levels higher than 15 cmH2O may be needed for some patients. Given concerns for the potential cardiopulmonary interactions, they do recommend following hemodynamics closely. The application of increased PEEP may have significant importance in future PARDS studies. It has recently been shown by Khemani et al.[377] that the use of PEEP settings lower than those recommended by the ARDS Network Protocol is associated with increased mortality in PARDS.

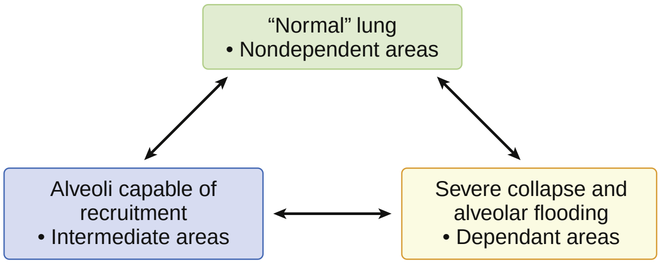
Some by extrapolation would consider the use of HFOV the most extreme form of tidal volume restriction. HFOV is able to prevent atelectasis by maintaining a constant airway pressure. Trauma from lung stretch is avoided by delivering tidal volumes that are less than anatomic dead space.[378] Unfortunately, there is very little information in pediatric mechanical ventilation with no recent randomized control trials. There have been two recent adult studies, but they did not yield results supportive of HFOV. OSCAR[357] was a negative study, and OSCILLATE[379] was stopped early for a potential increase in mortality in the HFOV group. Adult practitioners are likely moving away from HFOV and use in pediatrics remains regionalized to a few centers that continue its use. The PALICC guidelines leave HFOV as a potential rescue therapy.

There are further adjunctive therapies for PARDS that will require future studies to confirm their potential benefit. This list would include the use of corticosteroids, inhaled nitric oxide, ECMO, prone positioning, use of neuromuscular blockade, and the use of exogenous surfactant. There is insufficient data at this time to state these therapies should be routinely used for PARDS. Inhaled NO should be used for patients who have documented pulmonary hypertension or right heart dysfunction. The most recent published pediatric study of inhaled NO shows the possibility for harm.[380] The use of extracorporeal life support for PARDS has not been sufficiently studied to indicate it is beneficial. Further, given the complexity of the therapy, future trials may be very difficult, and to what extent ECMO is used for PARDS will vary based upon the individual institution.

As patients progress through their disease course and care is no longer increasing, the issue of weaning from mechanical ventilation and timing of extubation must be addressed. Various different strategies have been used to wean off of the ventilator to varying degrees of success. Likely one of the most effective strategies is the daily scheduled use of spontaneous breathing trials (SBTs) to assess whether a patient is ready for extubation.[381,382] Faustino et al. in 2018 published a secondary analysis of the RESTORE clinical trial.[383] Of patients requiring mechanical ventilation for lower respiratory tract disease, they found 43% passed their first extubation readiness. Of the group that passed an extubation readiness test, 66% were extubated within 10 hours. Many PICUs are using protocols to provide daily SBTs. In the right setting, the breathing trial can be performed safely by the respiratory therapy staff without physician input. In the near future, we will see an increase in computerized ventilation protocols driving care in the PICU. Without protocols, there is significant variability in usual care mechanical ventilation strategies,[384] and even with protocols, there can be poor adherence to protocols.[385] As a group, PICU intensivists would benefit from computer decision support and likely would accept some version of this.[386,387] Future studies will be needed to determine if we can find the Goldilocks version of ventilation protocols. We need to provide not so little mechanical ventilation that the patient is struggling to breathe. Yet, we must provide not so much that there is atrophy of the diaphragm.[388,389]

PRINCIPLES OF LUNG PROTECTIVE STRATEGIES: LIMITING VENTILATOR ASSOCIATED LUNG INJURY

As lung injury progresses, in response to pulmonary or extrapulmonary injury, the lungs can be divided into three hypothetical regions: (1) areas with severe collapse and alveolar flooding "dependent areas"; (2) recruitable areas with alveolar atelectasis "intermediate areas"; and (3) normal lung "nondependent areas" (Fig. 79.4). The goal of mechanical ventilation is to recruit intermediate areas, allowing improved gas exchange, spare normal areas of lung from ventilator associated lung injury (VALI), while giving dependent collapsed regions of lung with alveolar flooding time to recover from the primary process resolves (i.e., pneumonia, sepsis, etc.). Lung recruitment of intermediate areas and prevention of VALI is accomplished by using PEEP and limiting tidal volume and plateau pressures. This can be a complicated task, so let us first look at Fig. 79.5, and try to conceptualize a theoretical pressure-volume curve of the lung. As alveolar airway pressure increases, there is



"Normal" lung
• Nondependent areas
Alveoli capable of recruitment
• Intermediate areas
Severe collapse and alveolar flooding
• Dependant areas

an opening pressure (Pflex) required to overcome airway resistance and alveolar compliance (Compliance = ΔV/ΔP). Pressures below Pflex will lead to alveolar collapse, termed *atelectasis*. If airway pressure cycles above and below Pflex, alveoli will continually open and collapse, leading to wall shear stress and eventual damage: atelectrauma. Following the hysteresis curve to the upper extent of the inspiratory limb, as pressure increases, there comes a point termed, Pmax, whereby the alveoli start to become overdistended. Above Pmax, shear stress again leads to alveolar damage, this time termed *volutrauma*. Therefore, in theory, we attempt to keep tidal volumes on the most compliant part of the volume-pressure curve, above Pflex and below Pmax, leading to the idea called "open lung ventilation." Triggered by the ARDSnet's initial study, the use of low tidal volumes (6-8 mL/kg) with the addition of PEEP (open lung strategy) may reduce morbidity and mortality in patients with ARDS (Fig. 79.6).[390] However, as lung injury to the normal and intermediate areas of the lungs progresses, the volume-pressure curve moves to the right as the compliance of the lungs decreases, leaving a smaller therapeutic window requiring an increase in PEEP, resulting in higher MAP to maintain recruitment of areas of normal and recruitable lung (Fig. 79.7).

Lung protective strategy attempts to decrease VALI by inhibiting volutrauma, barotrauma, atelectrauma, oxygen toxicity, and biotrauma (Fig. 79.8).

Low Tidal Volume: Despite using usual control groups in the ARDSnet original study, employing a low tidal volume approach of 6 to 8 mL/kg has become a standard of care.

PEEP: The advantages of PEEP as a distending pressure include: increase in FRC, improvement of respiratory compliance, improvement of ventilation/perfusion mismatch, redistribution of lung water/edema. PEEP ultimately improves arterial oxygenation. The use of low tidal volumes has been consistent across multiple recent trials, but the selection of PEEP in these trials has been highly variable. Recent pediatric studies have shown that setting PEEP lower than the ARDSnet guidelines can result in increased mortality.[391] Further, guidelines from

the PALICC recommends increased levels of PEEP.[366] It can be difficult to determine the critical opening pressure of alveoli clinically. Therefore, most clinicians initially use a minimal distension strategy by setting PEEP between 5 and 9 cm H_2O, as lung injury progresses and hypoxemia worsens, PEEP may be increased to increase mean plateau pressures (keep $<$30-35 cm H_2O) and aid in recruitment. More precise methods of determining optimal PEEP in patients with ARDS include titration using dynamic compliance or static pressure-volume loops to identifying the critical opening pressure. Alternatively, one can use titration with dynamic compliance or static pressure-volume curve. Likely, in the future we will determine optimal PEEP in patients with ARDS use transpulmonary pressures with an esophageal catheter. It is important to remember that as PEEP is increased and lung is recruited, intrathoracic pressure is also increased. There has been concern by clinicians that increased intrathoracic pressure can inhibit cardiac output by reducing venous return. There have been a number of studies that have shown even with increasing PEEP there is not a decrease in cardiac output.[392,393] However, given the concern for decreased cardiac output, hemodynamics should be monitored as PEEP is increased.

Plateau Airway Pressures: Sustained plateau airway pressures greater than 35 cm H_2O can lead to barotrauma: pneumothorax, pneumomediastinum, and subcutaneous emphysema. In an attempt to limit barotrauma, $PaCO_2$ is allowed to increase in the face of inadequate minute ventilation. This permissible hypercapnia can be employed as long as the patient tolerates the acidosis and is able to buffer with the renal retention of HCO_3 and there are no contraindications from coexisting disease.

Driving Pressure: Driving pressure is the peak inspiratory pressure minus the PEEP for patients who are paralyzed and receiving mechanical ventilation. Amato et al.[394] demonstrated in a reanalysis of adult ARDS patients involved in prior randomized trials that decreases in driving pressure due to changes in ventilator management were strongly associated with increased survival.

Neuromuscular Blockade: Neuromuscular blocking agents (NMBA) have been provided to patients with ARDS to control ventilation and reduce trauma caused by increased tidal volume or increased airway pressure. NMBAs may also allow patients to tolerate higher levels of PEEP. This would lead to decreased trauma from repeated opening and closing of lung units. Further, NMBAs may reduce oxygen consumption from both skeletal and respiratory muscles. Papazian et al.[395] as part of the ACURASYS study demonstrated that early use of NMBA improved the adjusted 90-day survival with ARDS and increased the time off of the ventilator. They did not see an increase in muscle weakness with the use of cisatracurium. Pediatric trials looking at use of NMBAs have not yet been performed.

ADJUVANT THERAPIES FOR ACUTE RESPIRATORY DISTRESS SYNDROME

Prone Positioning

In pediatric patients, Curley et al.[396] demonstrated that prone positioning was associated with an improvement oxygenation in patients with ARDS. This group also showed proning can be safely applied in pediatric patients.[397] However, proning was not associated with a benefit in mortality or ventilator-free days, and the trial was stopped early for futility.[396] Prone positioning improves lung recruitment in select patients with ARDS. This may explain the difference between adult and pediatric results. In adults, Guerin et al.[398] performed a multicenter prospective randomized control trial, Proning Severe ARDS Patients (PROSEVA), which showed that early administration of prone positioning significantly decreased 28-day and 90-day mortality. Between these two studies, the pediatric patients were more heterogenous and the adults were homogenous with more severe ARDS. The impact of patient selection and duration of prone positioning is unclear; however, it is likely that a subgroup of patients, respond to prone positioning early after lung injury, and immediate responders may benefit from prolonged proned positioning.[399] Pediatric patients with brain injury and worsening hypoxemia prone positioning may be attempted with careful monitoring of ICP.[400,401] Future studies in pediatrics are needed.

Surfactant Therapy

Exogenous surfactant therapy is standard of care in neonates suffering from RDS; however, the utility of surfactant therapy in the treatment of ALI and ARDS is uncertain and continues to be researched. In pediatric patients, a 2003 study by Möller et al.[402] showed immediate improvement in oxygenation and a trend toward improved survival with the exogenous surfactant therapy, calfactant. However, Willson et al. in a recent randomized control trial found that surfactant did not improve oxygenation and decrease mortality relative to placebo administration.[403] However, there was no difference in length of mechanical ventilation or ICU stay. The current PALICC guidelines do not recommend routine use of surfactant.[366] Clinicians still feel that there still may be a specific pediatric patient population (i.e., near drowning victims) that still may benefit from exogenous surfactant administration, and research is ongoing to determine patient selection, timing, and combination with other therapies for treatment of ALI/ARDS.

Corticosteroids

A great percentage of pediatric patients with ARDS will receive corticosteroids at some point during their hospitalization. There are a number of underlying issues of inflammation and potentially adrenal insufficiency that would prompt clinicians to provide them. There were two pediatric studies published in 2015 that provide some insight. Drago et al.[404] published a small randomized placebo controlled trial of 35 patients with ARDS. There was no difference between groups with regard to duration of mechanical ventilation, length of ICU stay or mortality. They did find that it was feasible to provide low dose infusions of methylprednisolone without significant increases in nosocomial infections or serum glucose. Yehya et al.[405] reported a single center observational study in which 169 of 283 children with pediatric ARDS received corticosteroids for greater than 24 hours while receiving mechanical ventilation. The group that received steroids had fewer ventilator-free days and a longer duration of mechanical ventilation in survivors. Currently, the PALICC guidelines do not recommend routine therapy with corticosteroids for pediatric ARDS.[366]

Nitric Oxide

Inhaled nitric oxide (iNO) acts as a selective pulmonary vasodilator to improve V/Q mismatch, decrease pulmonary hypertension, and reduce right ventricular cardiac work. NO upregulates cGMP, ultimately resulting in smooth muscle relaxation and pulmonary arteriolar vasodilatation. iNO is delivered directly to ventilated lung units and improves perfusion in these areas of lung without significant effects on the rest of the pulmonary vascular bed, thereby improving V/Q mismatch and oxygenation in patients with ARDS. Much like prone positioning and surfactant therapy, NO can result in transient improvements in oxygenation. A systemic review and meta-analysis performed by Adhikari et al.[406] in adults with ARDS showed inhaled NO does not reduce mortality, regardless of severity of illness. In pediatrics, a small, randomized trial by Bronicki et al.[407] showed that pediatric patients with ARDS randomized to receive iNO had significantly improved ECMO-free survival and ventilator-free days at 28 days. This trial only had 55 total subjects and did not show a difference in overall mortality. The most recent study was a propensity matched cohort of 499 pediatric patients with ARDS by Bhalla et al.[380] There were a total of 143 that received iNO. They found that use of iNO was not associated with improvement in ventilator-free days or mortality. There still remains a role for iNO in patients with pulmonary hypertension, right heart dysfunction, and potentially a bridge to ECMO. Any further roles would require future studies to show benefit.

Extracorporeal Membrane Oxygenation

ECMO remains a rescue strategy for pediatric patients with ARDS that fail to respond to advanced modes of mechanical ventilation. There has been much more research with ECMO in adult ARDS as compared with pediatrics. The CESAR Trial in adults demonstrated improved outcomes in adults treated with ECMO; however, this trial had significant methodological flaws.[408] Results of the EOLIA (ECMO to rescue lung injury in severe ARDS) were reported in 2018.[409] The trial enrolled adults with very severe ARDS. They found that 60 day mortality was not significantly lower in the group randomized to ECMO as compared with conventional mechanical ventilation and possible use of ECMO as a rescue therapy. With regard to pediatric data, in 2018 Barbaro et al.[410] published a secondary propensity score matching analysis of ECMO use in patients from the RESTORE study. They found that in patients with severe pediatric ARDS there was not superior outcomes in the group treated with ECMO as compared with those that did not receive ECMO support. With improved care and research, presumably the mortality risk for both ECMO as well as ARDS will decrease. J. C. Lin[411] recently published a review on this topic which may provide additional insights. Further research regarding ECMO support of severe pediatric ARDS is needed.

ADJUNCTIVE PHARMACOLOGIC THERAPY: SEDATIVES AND ANALGESICS

Sedation is often required to help children cooperate with mechanical ventilation. The amount of sedation required depends on the child's age, size, underlying disease, and amount of respiratory support needed. Some children are neurologically depressed and require no sedation. Sedation allows patients to breathe "in phase" with the ventilator, which reduces the peak airway pressure and eliminates coughing and straining, all of which can cause pulmonary gas leaks or inadequate ventilation. Sedation has changed over the past many years in PICUs across the country. Part of the cause of this can be attributed to the development of protocols to limit sedation to decrease tolerance, withdrawal symptoms when sedation was weaned, and the potential for exacerbation of delirium. Many of the larger PICUs participated in the RESTORE study.[359] The RESTORE study can serve as a good example of how to deliver sedation using protocols. Each patient's level of sedation was titrated to a State Behavioral Scale, which allowed for a common language among care providers.[412] The medications that they used to provide sedation while patients were intubated were primarily morphine and midazolam. They recommended the use of fentanyl infusions as the opioid agent for patients that had hypotension or reactive airways disease. There were also secondary sedation agents that were used which included pentobarbital, ketamine, methadone, clonidine, dexmedetomidine, and propofol. Some institutions did use lorazepam as an alternative benzodiazepine. Pentobarbital and ketamine were adjunct medications when the patient was unresponsive or less responsive to the primary agents. Methadone and clonidine were adjuncts used primarily to prevent withdrawal symptoms as the patient was tapered off medications. Dexmedetomidine and propofol were used in this study as temporary agents to wean off other medications in anticipation of extubation. Propofol is not used in some units or only used as a temporary measure because of the concerns for propofol infusion syndrome.[413] Dexmedetomidine is seeing increased usage in PICUs across the country not just for short-term sedation. In some instances, it can replace opioids as a means of providing sedation. There should be a word of caution in administering lorazepam to premature neonates. Lorazepam repeatedly dosed over several days may cause steroid-responsive hypotension as a result of buildup of drug in the body. The half-life of lorazepam is approximately 72 hours in premature infants. Giving the drug every 4 to 6 hours causes accumulation of the drug in blood and tissues.

NMBAs increase chest wall compliance, reduce oxygen consumption, and facilitate mechanical ventilation. If neuromuscular blocking drugs are used, they should be administered in conjunction with medications that cause amnesia and anxiolysis and control pain. Vecuronium, rocuronium, and cisatracurium are the most commonly administered muscle relaxants used in the PICU (also see Chapter 27). Rocuronium is often given for intubation and for intermittent dosing. Vecuronium can be used as an intermittent agent but also as a continuous infusion. There are risks of decreased metabolism and prolonged clearance with vecuronium infusions and many will choose instead to use cisatracurium. Cisatracurium is often useful because its elimination is not dependent on renal or hepatic function. If these drugs are given for more than a day, provision of regular drug holidays should be considered to avoid serum buildup of the drug and prolonged paralysis.

WEANING FROM MECHANICAL VENTILATION

The pediatric literature falls behind adult publications with regard to guidance in weaning and extubation from mechanical ventilation. A 2009 review by Newth et al.[414]

addressed what was known at the time. Attempts have been made to develop predictive indices identifying which children can be successfully weaned from mechanical ventilation. Most of the indices are used in research but do have clinical applications. One indices is the Rapid Shallow Breathing Index (RSBI) from Yang and Tobin.[415] The RSBI is equal to the RR/tidal volume. When patients are breathing comfortably, they have a lower RR with larger tidal volumes. In this circumstance, the RSBI is a low number. Further, patients with respiratory distress tend to breathe more rapidly with smaller tidal volumes and hence have a higher RSBI. There are several different techniques for weaning from mechanical ventilation. These include lowering the set ventilator rate over time, performing a daily SBT, or increasing pressure support or CPAP sprints.[416] Many hospitals are initiating daily SBTs for their patients. These are periods of decreased ventilatory support while the patient is observed for evidence of respiratory distress. The decreased support can be pressure support, CPAP, or T-piece ventilation. Patients are observed to see that there is no significant increase in RR, decrease in saturations, diaphoresis, hemodynamic compromise, or evidence of increased work of breathing. The successful completion of a SBT will initiate of plans for extubation. Depending on the ICU, SBT are carried out under direction of the physicians or they can be independently performed by the respiratory therapist. It is possible that computerized weaning protocols will further reduce time on mechanical ventilation.[417] At the moment it seems that the best solution is to ask on a daily basis whether the patient is able to be extubated. Studies indicate a significant percentage of patients being evaluated for weaning are ready for extubation.[418]

We must keep in mind that as we are weaning patients from mechanical ventilation, there is an anticipated extubation failure rate. If we continue mechanical ventilation until we are absolutely certain a patient will not fail, many patients will be ventilated longer than necessary. A 2003 review[418] of 16 ICUs showed an extubation failure rate of 6.2% (range 1.5%-8.8%) for patients requiring mechanical ventilation longer than 48 hours. Our own research shows a reintubation rate of 8.3% following extubation.[286]

With regard to the degree of decreased ventilatory support during an SBT, use of CPAP does not put patients under increased stress. Multiple prior studies demonstrate that infants or children with smaller ETTs are not “breathing through a straw” when put on CPAP or T-piece.[419-422] Relative to an adult, the ETT may be smaller in diameter, but it is also shorter and the inspiratory flow rate in infants is low compared with an adult. Flow rates are measured to be approximately 0.5 L/kg/min.[421] Therefore, a 3 kg infant has a flow velocity of 1.5 L/min as compared with 30 L/min for a 60 kg adult. If patients are unable to successfully complete an SBT, it is possible they would not manage the work of breathing postextubation.

Overall, the criteria for extubation readiness includes intact airway reflexes, hemodynamic stability, manageable secretions, and an appropriate level of alertness. The amount of negative inspiratory force (NIF) the patient can generate can be measured. A NIF should be measured with a calibrated manometer and inspiration from residual volume. Typically, a NIF of negative 30 or more is associated with extubation success. The presence of a leak around the ETT may be supportive of extubation. There is some research showing the absence of a leak around the ETT does not predict extubation failure.[423,424] However, absence of a leak is associated with the development of subglottic upper airway obstruction after extubation.[286] Extubation failure is typically defined as reintubation less than 24 hours after a scheduled extubation attempt. Extubation failure may be caused by a multitude of reasons but large category is postextubation upper airway obstruction. We believe the incidence of upper airway obstruction to be between 37% and 41%.[286,418] As there is significant interobserver variability[286] in the clinical assessment of upper airway obstruction, physiology based tools may be valuable.[286] Objective measures of airway obstruction may be necessary before we have a definitive answer as to which therapies reduce subglottic narrowing and reduce obstruction.

RESPIRATORY DISORDERS

Laryngotracheobronchitis (Croup)

Croup occurs most frequently in the 3-month-old to 3-year-old age group. Croup is a viral infection (parainfluenza, influenza, adenovirus) that causes edema of the tissues in the upper airway, particularly in the immediate subglottic region. There is usually a history of a few days of upper respiratory tract infection symptoms followed by hoarseness, a croupy cough, and possibly stridor. The degree of respiratory distress and the child’s ability to compensate for the increased work of breathing are best assessed clinically. These patients are initially treated with mist and aerosolized racemic epinephrine to reduce swelling of upper airway mucosa.[425] Steroid administration is common yet controversial.[87] Tracheal intubation is required when the child can no longer sustain the increased work of breathing and CO_2 increases. When the trachea is intubated, the ETT should be 0.5 to 1.0 mm smaller than usual for age. The ETT must be of sufficient size that the patient can breathe easily during spontaneous ventilation and the nurses can effectively suction secretions from the airways. Croup usually resolves spontaneously in 3 to 7 days. The average duration of tracheal intubation is approximately 5 days. Laryngotracheobronchitis is less common in children older than 4 years.

Epiglottitis

Epiglottitis is an inflammation of the mucosa of the supraglottic structures that was previously caused by *Haemophilus influenzae* type B but is now commonly caused by *Staphylococcus aureus* and streptococcal organisms because immunization against the *Haemophilus* organism has been so effective. In the past, epiglottitis was a disease of 4- to 6-year-old children. Now, it occurs more commonly at older ages (even in adults).[426] In young children, epiglottitis is a true airway emergency because it may rapidly progress to complete and fatal airway obstruction. Providing a secure airway is the first priority. Children with epiglottitis appear toxic and have a fulminant onset of fever and respiratory distress. Tracheal intubation during anesthesia is commonly required until antibiotic therapy (ampicillin and chloramphenicol or ceftriaxone) is initiated and the signs of systemic toxicity subside. Introduction of the *H. influenzae* vaccine has dramatically decreased the incidence of *H. influenzae* infection, as well as that of other *H. influenzae* processes.[131]

Bronchiolitis

Bronchiolitis is an acute viral infection of the lower respiratory tract that occurs primarily during the first 2 years of life. The signs and symptoms of this malady are air trapping, wheezing, mild to moderate systemic hypoxemia, increased work of breathing, and increased airway resistance. The cause is usually an infection with respiratory syncytial virus (RSV).[427] Patients at high risk for respiratory failure from this disease include infants and young children with a history of prematurity, chronic lung disease, or congenital heart disease. Apnea is frequently the first sign of decompensation in neonates, which often occurs before significant hypercapnia appears. Fatigue is a common indication for mechanical ventilation. Treatment is primarily supportive and includes endotracheal intubation and mechanical ventilation for respiratory failure.[428] RSV immune globulin (RespiGam) is a prophylactic IV drug that is administered to patients at risk for seasonal RSV disease (ex-premature infants, infants with congenital heart disease, immunosuppressed patients, or those with multiple congenital anomalies); it has dramatically decreased the incidence of illness in this population. Ribavirin is a virostatic drug available for the treatment of children with RSV and congenital heart disease, immunosuppressive disease, or multiple congenital anomalies.

Cystic Fibrosis

Cystic fibrosis is a fatal autosomal recessive disease carried on chromosome 7. Although it affects the pancreatic, hepatic, pulmonary, GI, and reproductive systems, 90% of the reported morbidity and mortality is pulmonary.[142] The pulmonary pathology consists of severe airway obstruction, bronchiectasis, emphysema, and terminal respiratory failure.

Survival of patients with cystic fibrosis has improved dramatically over the past 30 years. More than one-third of patients survive to greater than 30 years of age.[143] This change is the result of improved antibiotic therapy, nutritional support, and aggressive treatment of complications. Lung transplantation has been performed in patients with chronic respiratory failure with varied success.[429,430]

Bronchopulmonary Dysplasia

BPD is a form of chronic lung disease that occurs in patients who have survived severe neonatal lung disease. The cause of this disease is uncertain, but usually patients were premature, had hyaline membrane disease, and required prolonged and aggressive respiratory support with high inflating and distending pressure and high oxygen concentrations. Inflammation appears to be an important component of this disease.[431] Children with BPD have decreased dynamic compliance, increased airway resistance, increased physiologic dead space, and markedly increased work of breathing. The lungs are hyperinflated, and there are intercostal retractions, nasal flaring, and wheezing. Chest radiographs demonstrate large lung volumes and fibrosis as well as cystic and atelectatic areas. Hypercapnia and hypoxia are present to varying degrees.[432,433] Therapy for BPD includes providing enough calories to meet the higher energy expenditure required for the increased work of breathing. Respiratory support (mechanical ventilation, CPAP) is required for some patients. Diuretics and bronchodilators are frequently used and may be associated with electrolyte abnormalities. Most long-term survivors have subjectively normal pulmonary function. However, some survivors have severe chronic physiologic changes.[434,435] During the first years of life, viral or bacterial pulmonary infections often increase the need for respiratory support; these infections may prove to be fatal. Great effort is being made to prevent BPD. Because the trauma of mechanical ventilation on an immature lung is thought to be the major cause of BPD, alternative modes of ventilatory support are being evaluated, including exogenous surfactant, high-frequency ventilation (especially HFOV),[436] ECMO, and liquid ventilation.[432,437]

Sleep Apnea

Normal ventilation during sleep requires normal upper airway anatomy and normal intact reflexes. The latter include central responses to hypercapnia and hypoxia, response to airway irritation, and dynamic phasic contraction of the pharyngeal and hypopharyngeal muscles. Sleep apnea usually occurs when one or more of these protective responses is abnormal. In infancy, sleep apnea is relatively common. Numerous causes have been postulated, the most attractive of which is immaturity of the medullary chemoreceptors. Patients with Ondine's curse, the most severe form of central apnea, have complete apnea when asleep. Lesser breathing disorders may be present during sleep in patients with sudden infant death syndrome. Treatment of sleep apnea consists of respiratory stimulants (theophylline), cardiorespiratory monitoring during sleep, and in some severe cases, tracheotomy and nighttime mechanical ventilation. Obstructive sleep apnea occurs in all pediatric age groups. It may be associated with an identifiable anatomic disorder, such as enlarged tonsils and adenoids, the Pierre Robin syndrome, and tracheal and laryngeal malacia. Signs and symptoms of obstructive sleep apnea include loud snoring, obstructive episodes with frequent arousal, behavior disorders caused by sleep deprivation, and cor pulmonale. The diagnosis is made by the history, ECG, and formal sleep studies. Bronchoscopy may also be helpful in defining the problem. In young children, an enlarged liver may suggest that the child has pulmonary hypertension. Treatment of sleep apnea includes removal or bypass of an obstruction. Although tonsillectomy and adenoidectomy may improve the airway, there may still be significant airway obstruction for the first few days after surgery. Rarely does such a child require a tracheostomy.

Foreign Body Aspiration

Foreign body aspiration is a relatively common and often catastrophic event in children. Although it can occur at any age, the peak incidence of foreign body aspiration occurs at 6 months to 3 years of age. Vegetable matter (peanuts) and other foodstuff (hot dogs) or coins and small pieces of toys are the most commonly aspirated material. Many of these objects are radiolucent. The symptoms of aspiration are related to the location of the foreign body within the airway and the time since the object was aspirated. Acute symptoms may include total airway obstruction, stridor, wheezing, or acute onset of coughing, whereas more chronic symptoms include bloody sputum, chronic coughing, or wheezing. The diagnosis of a foreign body in the airway is made from the history and physical examination and, in some cases, by radiologic imaging. The efficacy and safety of abdominal thrusts have been questioned. The Heimlich maneuver and back slaps are reserved for acute upper airway obstruction with no air movement. Treatment of less acute or lower airway foreign body aspiration includes bronchoscopy, postural drainage, chest physical therapy, bronchodilators, and surgical removal of the object.[438]

Upper Airway Obstruction and Meningomyelocele

Vocal cord paralysis is a common result of several disorders, including brainstem abnormalities and myelodysplasia. Children with meningomyelocele usually have an Arnold-Chiari malformation and may have stridor. This lesion allows caudal displacement of the medulla, stretching of the cranial nerve tracts, and abnormal arterial architecture of the brainstem. Vocal cord paralysis may result from pressure on the brainstem (i.e., with hydrocephalus) or from focal infarcts of the brainstem. Treatment of these brainstem abnormalities includes relief of the hydrocephalus and, if the paralysis persists, cervical decompression of the Arnold-Chiari lesion. Despite these surgical procedures, some children require a tracheotomy and long-term mechanical ventilation.

ASTHMA

The prevalence of childhood asthma is increasing over time. Estimates from the Centers for Disease Control and Prevention placed the percentage of children with asthma at 3.6% in 1980 5.8% in 2003 and 9.5% in 2011 (www.cdc.gov/nchs/fastats/asthma.htm). Thankfully, the majority of children with asthma will never require intensive care. However, for the children that do there can be significant morbidity and a risk of mortality. In a 2012 study by Newth et al.[439] of fatal and near-fatal asthma in an ICU setting, 12% of patients had complications and the mortality was 4%. Cardiac arrest prior to admission occurred in 10 of the 11 patients who died. For the purposes of this section critical asthma is defined as an asthma exacerbation requiring ICU admission.

Asthma is a disease of inflammation. There is infiltration of the submucosal area of the airways with mast cells, eosinophils and CD4 lymphocytes. Degranulation of mast cells releases leukotrienes and histamine causing edema, increases in mucus production, and chemotaxis of white blood cells (WBCs). Multiple factors can trigger an asthma attacks and degranulations of mast cells. Such factors include allergens, infections (viral > bacterial), changes in the weather, and strong emotions. Inflammation increases irritability of the airway as well as airway hyper responsiveness. The airway lumen is decreased by spasm of the bronchial muscles, edema, and mucus. Decreases in the airway lumen significantly increase airway resistance. For laminar airflow, airway resistance is related to the third power of the radius, but with turbulent airflow it is related to the fourth power. Due to the smaller lumen of their airways, children experience much greater changes in airway resistance during asthma attacks than adults. Due to resistance in exhalation, an expiratory wheeze is typically noted. Bronchospasm, edema, or mucus plugging can lead to complete obstruction of small airways. Hypoxemia occurs as a result of a mismatch in ventilation and perfusion. Airway dead space is increased by obstruction of the airways. To maintain ventilation, the RR is typically increased. In turn, the initial $PaCO_2$ is usually low. Respiratory fatigue or impending failure may be identified by a normal or elevated $PaCO_2$.

It should be reinforced early that wheezing is caused more things than just asthma and that asthma can occur without wheezing. Wheezing is the sound that is produced when there is obstruction to airflow. Wheezing can be caused by pneumonia, upper airway obstruction, foreign body aspiration, and CHF. Each would require different therapy. Wheezing in a toddler of a sudden onset should prompt evaluation for foreign body aspiration. The history should be addressed at recent choking or coughing episodes. Even the presence of a history of reactive airways or atopy does not rule out aspiration. A high index of suspicion should be maintained. Intermittently a chest-ray obtained for a child who is wheezing shows cardiomegaly rather than peribronchial cuffing. Asthma is statistically more likely but this can be the presentation of heart failure. In turn, a chest x-ray is warranted for any patient with their first presentation of wheezing patient and certainly for any child who is admitted to the ICU for wheezing. With regard to asthma that occurs without wheezing, the movement of air is required to hear wheezing. It is possible to have such significant airflow restrictions that patients don't produce audible wheezing. Patients who present with a quiet chest or limited airflow on auscultation require immediate action.

Children presenting with an asthma exacerbation may have a few days of URI symptoms followed by increased work of breathing. The patient may have low room air oxygen saturations. The patient's position of comfort may be sitting up to support their muscles of respiration. Accessory muscle use is noted. There is a prolonged expiratory phase on auscultation. Some children in an effort to increase airway pressure may be breathing out with pursed lips or in smaller children grunting may be noted. The child may not be able to speak in more than one or two word phrases. Therapy should be started immediately first with supplemental oxygen to address hypoxemia. If the child mild respiratory distress, nasal cannula oxygen may be sufficient. If the child has moderate or severe respiratory distress, oxygen should be delivered by either face mask or non-rebreather face mask. Inhaled beta agonists such as albuterol are given to relax bronchial smooth muscles. IV or subcutaneous terbutaline or epinephrine may be required if there is not enough air movement to deliver inhaled medications. Steroids should be given early as the effect will take some time. If there is limited improvement with initial therapy arrangements should be made for ICU admission. Many emergency departments will attempt to obtain arterial blood gases. However, the clinical picture alone may provide enough information to guide therapy.

Asthma Therapy

Supplemental Oxygen. Oxygen can be delivered with a standard nasal cannula, but the FiO_2 is limited. Standard nasal cannula might provide up to 28% FiO_2. Increasing the flow of oxygen with a standard cannula above 4 to 5 LPM is not usually tolerated. A simple face mask might increase the FiO_2 to 50%. A tightly sealed non-rebreather face masks might be able to provide a FiO_2 closer to 1. Providing oxygen with a HFHNC may provide nearly complete humidification of the airway gases and the FiO_2 also approaches 1. A 2014 study by Rubin et al.[440] demonstrated a decrease in effort of breathing in patients receiving HFHNC. The mechanism of its effect is not elucidated. Some clinicians have begun using HFHNC as a mechanism for delivery of beta agonists or other aerosolized medications, but there is not yet data supporting its use.

Inhaled β Agonists. Inhaled β agonists are used to relax bronchial smooth muscles. The most commonly used β agonists is albuterol, which is a racemic mixture of the active R and inactive S enantiomer. Levalbuterol, the active R enantiomer, is available as a separate preparation, but recent studies have not shown it to be more effective[441] or have less elevations in HR.[442] Albuterol is β_2 selective and comes as a metered dose inhaler or solution for nebulization. For initial therapy in the ICU, continuous albuterol is preferred, and the usual dose is 0.15 to 0.5 mg/kg/h or 10 to 20 mg/h. After improvement in air movement with decreased respiratory distress, intermittent doses can be given every 1 to 2 hours. Terbutaline as an inhaled medication is less β_2 selective compared with albuterol and therefore is used less commonly. Terbutaline remains as an important IV medication. Tachycardia is commonly associated with albuterol use. At times it is unclear if the elevated HR is related to toxicity of medications or due to ongoing respiratory distress. Arrhythmias may be seen with albuterol use but this is usually just an increased frequency of PVC. Diastolic hypotension is observed with higher doses of albuterol, although this can be related to decreased intravascular volume and increased intrathoracic pressure. Agitation and tremors can be seen with CNS stimulation. Hypokalemia may be noted as the Beta agonists drive potassium into cells. Ipratropium bromide, an inhaled anticholinergic, is sometimes paired with intermittent albuterol doses. Ipratropium bromide has the benefit of promoting bronchodilation without decreasing mucociliary clearance.

Corticosteroids. IV steroids are preferred to oral dosing in the ICU due to the possibility of decreased absorption or delayed onset. Methylprednisolone is used commonly due to its limited mineralocorticoid effects. The initial dose is 2 mg/kg and then 0.5 to 1 mg/kg every 6 hours. There may be regional preference for dexamethasone or hydrocortisone. Steroids are typically given for the duration of the acute asthma phase. If steroids are given for 5 days or less, they are not usually tapered. Systemic steroid use is associated with hyperglycemia, hypertension and occasionally agitation. In the initial ICU care inhaled steroids are of no benefit.

Intravenous Fluids. Children admitted to the ICU with critical asthma will likely be dehydrated from limited oral intake during their illness and increased insensible losses from the higher RR. The patient's circulating volume should be supported with fluid boluses if needed. However, excessive fluids should be avoided as this could lead to pulmonary edema. Pulmonary edema could worsen both oxygenation and airway resistance. Fluid boluses may also be needed for children whose respiratory distress progresses require mechanical ventilation. Hypotension often occurs during intubation.

Intravenous and Subcutaneous β Agonists. A significant decrease in air exchange may result in poor delivery of inhaled medications and IV β agonists may be required. Terbutaline is often the first choice of the available beta agonists. Terbutaline is relatively β_2 selective as compared with isoproterenol and epinephrine. Terbutaline can be given subcutaneously for children without IV access as a dose of 0.01 mg/kg/dose up to a maximum of 0.3 mg. IV terbutaline is loaded at a dose of 10 μg/kg over 10 to 20 minutes followed by a continuous infusion of terbutaline in a range of 0.1 to 10 μg/kg/min. The infusion can be titrated to effect. Subcutaneous epinephrine may be given for severe asthma exacerbation with limited IV access with a dose of 0.01 mg/kg of to the 1:1000 solution with a maximum dose of 0.5 mg. Absorption of the drug may be limited by poor perfusion to extremities. IV epinephrine may be an ideal drug for mechanically ventilated patients with hypotension. The use of isoproterenol in critical asthma has decreased over time.

Methylxanthines. There is regional variation in the use of the methylxanthine aminophylline in place of IV terbutaline as a second line drug for critical asthma. Fewer children with asthma are admitted to the ICU with a methylxanthine as a chronic medication. There are improved controller medications including the leukotriene inhibitors so fewer children are receiving oral theophylline. The methylxanthines promote bronchial smooth muscle relaxation, but the exact mechanism of action is not known. IV aminophylline is loaded at a dose of 5 to 7 mg/kg over 30 minutes, followed by a continuous infusion in the range of 0.5 to 0.9 mg/kg/h. If the patient has taken oral theophylline in the past 24 hours, the loading dose is reduced by 50% or the aminophylline dosing is adjusted based on a serum theophylline level. In general, an aminophylline loading dose of 1 mg/kg will raise the serum theophylline level by 2 μg/mL. The target range for serum theophylline in acute asthma is 10 to 20 μg/mL. Theophylline has a very narrow therapeutic window. Theophylline levels above 20 μg/mL are associated with nausea, tachycardia, restlessness, or irritability. Higher theophylline levels have been associated with seizure activity.

Magnesium. Magnesium can be given as an inhaled or IV medication to relax bronchial muscles. Smooth muscle relaxation occurs due to magnesium's effect as a calcium channel blocker. Results from the 2013 MAGNEsium Trial in Children (MAGNETIC)[443] indicate nebulized magnesium may be beneficial in an acute severe asthma exacerbation. There is some evidence that IV magnesium may also be beneficial in severe asthma.[444,445] As there is still regional variation to magnesium, at the least a magnesium level should be checked with the initial set of electrolytes and hypomagnesium should be treated. The dose for critical asthma and hypomagnesium can be the same 25 to 45 mg/kg given over 30 minutes. Magnesium toxicity can include muscle weakness, cardiac arrhythmias, decreased reflexes, and respiratory depression.

Helium. Mixtures of helium and oxygen (heliox) can be used to improve laminar gas flow. This occurs due to the decreased density of helium as compared with nitrogen (approximately one-seventh). For Helium to be beneficial in small airways, it must occur in a high ration with oxygen. The greatest benefits may be seen with an 80:20 or 70:30 ratio of helium:oxygen. Therefore, hypoxemia and the need for increased supplemental oxygen may limit heliox use. There is data supporting the use of heliox as a method of delivering inhaled β_2 agonists.[446] As with other advanced therapy, helium may not have a role in routine care, but there may be benefit from its use in severe critical asthma.

Ketamine. Ketamine is a noncompetitive N-methyl-D-aspartate (NMDA) receptor antagonist that can produce a state of dissociative anesthesia. An additional effect of ketamine is bronchodilation. It is a useful medication for sedation in the ICU as ketamine has limited effect on the respiratory drive, and in usual doses, hemodynamics are not usually affected. For patients with asthma who are intubated and mechanically ventilated, ketamine may be a good choice for sedation along with a benzodiazepine. Further, there was one pediatric study[447] showing an improvement in the PaO_2/FiO_2 ratio as well as dynamic compliance in mechanically ventilated children with refractory bronchospasm who were receiving a continuous infusion of Ketamine. There has been no study to show whether ketamine used to treat anxiety is beneficial in preventing intubation in patients during an asthma attack. For non-intubated patients, a recent Cochrane Database Review[448] did not show significant benefit in severe acute asthma. If a decision is made to use ketamine either for a procedure or a means of sedation, the bolus dose is usually 1 mg/kg, allowing time for effect before repeating. Ketamine is given as a continuous infusion at the dose of 5 to 30 μg/kg/min titrated to effect. One of the additional side effects of ketamine can be dysphoria, and as such it is usually given with a benzodiazepine.

Noninvasive Ventilation. There is very limited evidence that NIV is effective in children with asthma.[335] Clinically patients with effective air exchange who fight the mask and positive pressure do not benefit from NIV. Nevertheless, some children with very limited air exchange and fatigue take to NIV easily and appear more comfortable. NIV may allow time for therapies to become effective (steroids) and may prevent intubation. This should not be used when the level of alertness or ability to protect the airway is diminished.

Intubation. By the time patients with asthma require intubation and mechanical, they are hypoxemic, acidotic, fatigued, and have limited reserve. It is suggested that the most experienced person available perform the intubation. Appropriate venous access is required, and fluid boluses may be necessary. Ketamine and a benzodiazepine have been recommended by many. Ketamine may produce increased secretions, so atropine should be considered. Ketamine may produce dysphoria so the benzodiazepine is given for its amnestic effects. The management style in our ICU is to get the patient back to breathing spontaneously or initiating their own breathes as soon as possible after intubation. In turn, Rocuronium can be considered as medium short-acting muscle relaxant. Succinylcholine can be used, but the other side effects of this medication, including elevation of potassium, should be considered. A cuffed ETT is recommended, as ventilator settings may require high peak pressures. Immediately after intubation, we typically hand ventilate the patient with a low rate. This is to prevent alveolar overdistension and reduce the risk of pneumothorax. There can be acute decompensation following intubation. Hypovolemia and increased intrathoracic pressures may be an issue. Following the DOPE acronym, one should also look for **Displacement** or **Obstruction** of the ETT and rule out **Pneumothorax** or **Equipment** failure.

Mechanical Ventilation. There can be controversy regarding the best means to mechanically ventilate patients with asthma. The argument against setting the ventilator in a pressure control mode is that changes in airway resistance that occur with asthma can result in delivery of an inadequate tidal volume. The argument against a the ventilator in a volume control mode is that due to flow patterns of the ventilator the same tidal volume can be delivered with a higher peak pressure as compared with a pressure control mode. As stated before, our management style is to get intubated asthmatics breathing spontaneously as soon as possible. This allows them to set their own breathing rate, and on pressure support and PEEP, they can set their own inspiratory to expiratory ratio. Pressure support has been recommended because it is patient-initiated, even if not patient-limited.[449] There may be initial elevations in $PaCO_2$, but if the patient is well oxygenated, the carbon dioxide elevation is usually well tolerated.

Historically, clinicians set zero or low PEEP for intubated asthmatics due to the perceived risk of hyperinflation[450] and barotrauma. However, since 1988 there have been four adult studies[451-454] and one pediatric study[277] strongly suggesting the benefits of extrinsic PEEP during mechanical ventilation for intubated asthmatics. These studies demonstrated that extrinsic PEEP, up to a level to matching intrinsic PEEP, improves the triggering sensitivity of the ventilator, diminishes ventilatory work, and reduces mechanical work of breathing for patients spontaneously breathing with assisted ventilation. As the work of breathing is reduced, there is improved patient comfort and potentially a reduced need for sedation. It is felt that matching extrinsic PEEP applied with the ventilator to the intrinsic PEEP developed by the patient with asthma may improve delivery of aerosol therapy via the ETT. Matching PEEP may possibly result in earlier liberation from mechanical ventilation. It should be noted that some clinicians believe that attempts to match PEEP may include the risk that extrinsic PEEP will cause overdistension of the lungs. Overdistension of the lungs may increase the risk of hyperinflation and air leak syndrome.[450] Our studies[277,287] indicate that spontaneous breathing with pressure support and PEEP lowers WOB. For the individual patient, the level of extrinsic PEEP at which hyperinflation will occur is unknown. Theoretically, for the spontaneously breathing patient, extrinsic PEEP applied to counteract intrinsic PEEP should not cause an increase in end-expiratory lung volume (EELV) until extrinsic PEEP exceeds intrinsic PEEP.[455] Further, the EELV may even decrease, leading to decreased dead space and increased compliance. In our ICU intrinsic, PEEP is measured during a ventilator pause, allowing the patient to exhale completely and measuring the pressure before the next breath. We gradually add extrinsic PEEP with the ventilator and observe RR and clinical work of breathing. We always keep extrinsic PEEP at a level below intrinsic PEEP. We continue to reassess the level of extrinsic and intrinsic PEEP as the patient responds to therapy. Further research is needed to determine the best practice of mechanical ventilation for intubated asthmatics, but this is limited by the small number requiring intubation each year.

Inhalational Anesthetics. One of the properties of inhaled anesthetics is bronchodilation. In turn, inhaled anesthetics have been used as rescue therapy in children with critical asthma who are intubated. We have used isoflurane in our ICU for its reduction in bronchospasm with the added benefit of a decreased sedation requirement. However, inhaled anesthetics are difficult to use in an ICU setting. Modern ICU ventilators are not designed to accept a vaporizer. There is no circle system in ICU ventilators, so there is a tremendous use of anesthetic vapor. There is no primary means of gas scavenging in an ICU ventilator, so significant steps must be taken to contamination of the patient room. There is a case series of six patients reported by Wheeler et al.[456] Dr. J. Tobias has published several articles[457-459] detailing the use of inhaled anesthetics in asthma and other clinical conditions. A recent retrospective cohort study by Char et al.[460] in intubated asthmatics did not demonstrate a difference in mortality between centers that did or did not use inhaled anesthetics. There was significantly greater length of mechanical ventilation, greater length of stay, and increased hospital charges in the centers using inhaled anesthetics. The significant expertise needed to safely deliver inhaled anesthetics may limit its use to a few centers. An anesthetic conserving device (AnaConDa Sedana Medical) is available in the European market but not the United States. The device is a miniature vaporizer and a conserving medium or reflective filter that keeps the inhaled anesthetic on the patient side of the device. This device can be used with a normal ventilator. Finally, as the scientific community learns more about the potential neurotoxicity with inhaled anesthetics, the physician must weigh the risk and benefit profile to long-term inhalational anesthetics for the management of status asthmaticus.

Extra Corporeal Life Support for Status Asthmaticus. ECLS has been used as a rescue therapy in near fatal asthma. As with inhaled anesthetics, the use of ECLS for this indication is likely limited to a small number of centers. One single center study reports[35] their use, but the number of patients (13 total) is too small to determine whether this therapy has advantages over mechanical ventilation or conventional therapy.

Pulmonary Hypertension

CENTRAL NERVOUS SYSTEM

Systemic illness is a common cause of CNS dysfunction in infants and children. Seizures, head trauma, CNS infections, and hypoxic or metabolic encephalopathy commonly cause acute neurologic dysfunction in the PICU. Assessment of neurologic function depends on an understanding of the age-dependent progression of motor and cognitive skills. Table 79.8 lists the developmental milestones.

TABLE 79.8 Normal Ages for Major Developmental Milestones

Age	Motor Function	Language	Adaptive Behavior
4-6 weeks	Lifts head from prone position and turns from side to side	Cries	Smiles
4 months	Shows no head lag when pulled to sitting from supine position; tries to grasp large objects	Utters sounds of pleasure	Smiles, laughs aloud, and shows pleasure from familiar objects or persons
5 months	Grasps voluntarily with both hands; plays with toes	Makes primitive sounds	Smiles at self in mirror (ah, goo)
6 months	Grasps with one hand; rolls prone to supine; sits with support	His increased range of sounds	Expresses displeasure and food preferences
8 months	Sits without support; transfers objects from hand to hand; rolls supine to prone	Combines syllables (baba, dada, mama)	Responds to "No"
10 months	Sits well; crawls; stands holding; finger-thumb apposition in picking up small objects		Waves goodbye; plays patty-cake and peek-a-boo
12 months	Stands holding; walks with support	Says two or three words with meaning	Understands names of objects; shows interest in pictures
15 months	Walks alone	Utters several intelligible words	Requests by pointing; imitates
18 months	Walks up and down stairs holding; removes clothes	Says many intelligible words	Carries out simple commands
2 years	Walks up and down stairs by self; runs	Makes two- or three-word phrases	Engages in organized play; points to some parts of the body

Functional Postnatal Neurologic Development

Motor function in the newborn depends on gestational rather than postnatal age. That is, an infant born at 28 weeks' gestation exhibits motor responses similar to those of a full-term newborn when the former is 3 months old. Although potentially modifiable by cortical influence, most neonatal motor behavior is subcortically controlled, which permits normal motor behavior in newborns who have severe cortical damage. Assessment of intellectual development is difficult in a newborn; initially, it is based on the absence of reflexes and the acquisition of new motor skills. Adaptive or interactive behavior is first seen with accommodation to repeated stimuli and eye contact. The infant's intellectual development depends on the presence of external stimulation and social interaction, preferably from one or a few individuals. This is why infants and children who require long-term intensive care must have parental input and developmental stimulus.

Assessment of Neurologic Function

Clinical examination is the most important tool we have for assessing neurologic function in children. In an awake child, interactions with the examiner and caretakers are sensitive indicators of high or integrative cortical function. When the child's cognitive function is depressed from disease or drugs, examination of the general level of activity and peripheral and brainstem reflexes becomes an important, albeit crude, measure of CNS function. A detailed examination includes an evaluation of the level of consciousness and alertness in the context of sedative medications. The Glasgow Coma Scale (GCS) is a commonly accepted tool to evaluate the level of function of neurologically impaired patients (Table 79.9); however, it was not developed for this purpose, and extensive research needs to continue on directed scales and noninvasive means to improve assessment consciousness in the critically ill child.[461] Painful stimulation can stimulate both decorticate or decerebrate posturing and likely indicates significant CNS malfunction and should trigger further investigation. Decerebrate posturing is an extension at the elbows with the arms and hands pronated, whereas decorticate posturing of the upper extremities is flexion at the elbows with the hands clenched. These responses to painful stimuli or no response at all should (in combination with attempts to elicit a cough, gag, or ability to handle oral secretions) make the practitioner question whether the patient can protect their airway. Pupillary reflex is a well preserved function, and therefore unreactive pupils are very concerning. Large reactive pupils may be caused by tricyclic antidepressant ingestion, atropine administration, or a symptom of pharmacologic withdrawal. Small reactive pupils may indicate damage at the level of the pons, but usually indicate the presence of opioids or barbiturates. Fundoscopic exam is important to assess for signs of increased ICP or retinal hemorrhage; however, the bedside practitioner may have difficulty with these assessments, and it may require an ophthalmologist consultation.

Laboratory Assessment of Neurologic Function

The EEG is used to diagnose seizures and isoelectric brain death and to monitor the effects of barbiturates administered to induce coma. In addition, continuous EEG monitoring is often used to detect nonconvulsive seizure activity in critically ill children.[226,462,463] This is a resource-intense monitoring system that has yet to show that it improves

TABLE 79.9 Glasgow Coma Scale for Infants and Children

Activity	Adult/Child Response	Infant Response	Score
Eye opening (E)	Spontaneous	Spontaneous	4
	To verbal stimuli	To verbal stimuli	3
	To pain	To pain	2
	None	None	1
Best verbal response (V)	Oriented, appropriate	Coos and babbles	5
	Confused conversation	Irritable cries	4
	Inappropriate words	Cries to pain	3
	Incomprehensible words	Moans to pain	2
	None	None	1
Best motor response (M)	Obeys verbal command	Normal movement	6
	Localizes stimulus	Withdraws upon touch	5
	Withdraws from noxious stimulus	Withdraws upon pain	4
	Decorticate flexion	Decorticate flexion	3
	Decerebrate extension	Decerebrate extension	2
	None (flaccid)	None (flaccid)	1

outcomes; however, its use continues to grow in neonatal and pediatric critical care, and further study is needed for this promising noninvasive tool. CT allows rapid detection of CNS lesions, the extent of structural injury, and noninvasive assessment of ICP. Cranial ultrasound is a bedside technique used to assess ventricular size and intracranial anatomy in infants with nonfused cranial sutures. MRI permits intraorbital and ocular injuries and brainstem and spinal cord lesions to be examined; it is also good for defining soft tissue abnormalities.[464] MRI's major drawback is the length of time required for each examination and the relative inaccessibility of the patient while in the scanner. Maintaining body temperature can also be a problem in small children during MRI scanning because the room must be cold. It may be difficult to safely perform MRI in patients who have significant cardiorespiratory compromise because many of the pumps and ventilators cannot enter the scanner. Doppler ultrasound allows bedside assessment of CBF velocity in the ICU. Although it does not directly measure CBF, Doppler ultrasound is a useful bedside guide to therapy. CBF scans are the "gold standard" and are usually required to diagnose brain death during barbiturate coma. ICP can be monitored by inserting a catheter into a lateral ventricle or by inserting a subarachnoid screw or transducer into the epidural space or cerebral parenchyma. The ventricular catheter provides an accurate waveform and permits withdrawal of cerebrospinal fluid (CSF) to reduce ICP. The other devices used to measure ICP provide less consistent pressure waves and do not permit removal of CSF.

Traumatic Brain Injury

Despite advances in resuscitation care, morbidity following pediatric TBI remains high. TBI is composed of two components, an initial primary injury due to direct mechanical deformation of brain parenchyma, and a subsequent secondary injury that may develop over hours to days. Secondary injury may be the result of multiple mechanisms including ischemia, excitotoxicity, metabolic failure and eventual apoptosis, cerebral swelling, axonal injury, and inflammation and regeneration.[465] For improvements in outcome to be achieved in the pediatric critical care setting, secondary brain injury must be prevented or minimized.

Conventional wisdom about TBI has dictated that ischemia plays a major role in secondary brain injury. While reversal of ischemia is crucial, simply delivering oxygen to injured areas of the brain does not abate the onslaught of secondary injury cascades destroying vulnerable areas of brain following TBI. Recent evidence suggests that secondary injury persists despite adequate oxygen delivery to brain tissue due to persistent metabolic crisis.[466,467] Furthermore, hyperoxia is not effective in completely reversing metabolic crisis and may lead to persistent secondary injury due to superoxide and free radical generation. There is widespread heterogeneity of metabolism following TBI, with some regional areas of increased glucose and oxygen utilization (likely due to electrical instability); however, in large regions of the brain, oxidative metabolism is reduced to a critical threshold with critically low rates of $CMRO_2$.[468] This coupled with ongoing low CBF following TBI places viable brain tissue at risk.[468,469] How the neurovascular bundle regulates the delivery of blood flow to regions gripped in metabolic crisis in ongoing secondary crisis and determining how to manipulate CBF remains an important avenue of study in the immature brain.

Cerebral Perfusion Pressure and Cerebral Blood Flow

In children, developing effective treatments for TBI is complicated by the rapid changing responses of the immature brain to each type of brain injury during development from infancy through childhood.[470,471] Therefore, evaluation of therapies for children with brain injury must utilize immature animal models as a translational pathway to human trials in children. It must be understood that much of the research in this field that drives clinical guidelines and recommendations are born from adult clinical studies and adult aged small animal research. How this evidence translates to the child provides some direction but should catalyze further research focusing on the immature brain. This is especially true when the practitioner must indirectly target metabolic delivery in the face of secondary brain injury by attempting to modulate CBF and predict regulation or lack of regulation in the neurovascular bundle. Even in the healthy brain, CVR regulation is complex and poorly understood.[472-474] To add to this layer of complexity, CVR is likely heterogenous following brain injury dependent on the mechanisms of injury, age, and even gender. Optimal global CBF is an elusive clinical target, with a lower inflection point associated with ischemic injury and an upper inflection point associated with hyperemia increasing cerebral blood volume and ICP. In early posttraumatic brain injury, cerebral hypoperfusion may greatly contribute to secondary brain injury, ultimately increasing morbidity and mortality.[469,475] In adults, areas of contusions have low CBF similar to the ischemic penumbral zones surrounding areas of acute ischemic stroke.[476,477] Low CBF states have been demonstrated in children by xenon CT scans following TBI within 24 hours of the initial injury, but by 48 hours these patients had normal or supernormal blood flows.[475] Furthermore, CBF in pediatric patients as a target for neuro-resuscitation is a theoretical point of manipulation due to limited options of continuous measurement in the clinical setting. Therefore, CPP (mean arterial blood pressure [MAP] minus ICP) is a commonly used surrogate.

When cerebral autoregulation is impaired, CBF and the metabolic needs of the injured brain may depend on maintaining adequate CPP. The difficulty comes in identifying the term adequate. Currently, pediatric CPP thresholds (40-60 mm Hg) have been extrapolated from adult experimental and clinical TBI and stroke studies.[476,478] However, recently it has been reported in adults that ischemia following TBI may occur at much higher levels of CBF compared with stroke.[476] Chambers et al, have published much needed age-specific pediatric thresholds for critical CPP, below which cerebral ischemia occurs with unfavorable neurologic outcomes and increased mortality.[479-481] These studies identified inadequate CPP levels but did not identify an "optimal treatment" CPP, and therefore assumed that these CPP levels were equivalent to brain injury insult thresholds.

It is not clear if a CPP of 40 mm Hg is a minimal threshold and/or that an optimal CPP to prevent brain injury may be higher.[482] Using currently accepted pediatric CPP guidelines (CPP >40 mm Hg) may not ensure adequate oxygen delivery to brain tissue.[483,484] This raises the question: is a CPP greater than 40 mm Hg in the pediatric TBI patient high enough? Mild induced hypertension after ischemic stroke has shown promise in animal models but remains controversial in the clinical setting.[485,486] Adult TBI studies have observed an increased risk of adult RDS associated with targeting a CPP greater than 70 mm Hg, but it is unclear how applicable this is to pediatric neurocritical care.[487,488] A retrospective study of 146 pediatric TBI patients observed a strong association of poor outcome at discharge with hypotension within the first 6 hours of injury.[489] The window for treatment of hypoperfusion appears to be early after pediatric TBI, and may be of relatively short duration in children. We believe that early aggressive intervention of blood pressure support especially during early critical periods, such as initial resuscitation of a multitrauma patient, intubation, placement of support lines and neuromonitoring devices is critical to neuro-resuscitation. Guidelines released in 2012, based on Class III evidence for pediatric traumatic brain injury, suggest that a minimum CPP of 40 mm Hg should be maintained and that 50 mm Hg for a minimum CPP in older children may be required.[490] However, data in our laboratory in large animal models of TBI may support the use of higher CPP support (>70 mm Hg) in severe TBI.[491]

Targeting CPP often requires vasopressor support. While central venous access should not delay administration of vasopressor support, it is important to understand the risks of extravasation of these infusions and have qualified individuals place central venous access as soon as possible to mitigate these risks. Initial stabilization of the pediatric TBI patient may occur in limited resource environments where complex invasive intracranial monitoring may not be available. Early stabilization of cerebrovascular hemodynamics with phenylephrine and targeting a higher MAP or CPP may reduce brain injury and improve long-term outcomes. A common first-line vasopressor to improve MAP in pediatric brain injury is phenylephrine. Phenylephrine is an α adrenergic agonist that may have little or no effect on cerebral vasculature resistance.[492-495] Another vasoactive medication gaining favor is NE. NE primarily targets alpha-receptors for peripheral vasoconstriction, but has additional effects on β-receptors increasing inotropy. There are several published reports now in adults that show the rising use of NE as a preferred vasoactive medication and may provide more predictable CPP augmentation when compared with dopamine.[496-498] Prathep et al. have reported that adults with isolated traumatic brain injury and cardiac dysfunction have a higher incidence of in-hospital mortality.[499] Further research is critical to determine the degree of cardiovascular compromise following TBI in children and which vasopressor should be considered a first-line agent in pediatric brain injury; this currently should be determined by local experience and comfort of use. We believe that the next generation of treatments will build upon the tenets of ischemic neuro-resusciation and combine early directed metabolic neuroresuscitation.[500]

Respiratory Management in the Brain Injured Child

Airway Management. The comatose and brain-injured patient is at severe risk for respiratory failure due to loss of airway protective reflexes and impaired central regulation of respiratory function. In addition, progression of ALI and ARDS can be exacerbated by concomitant injuries (pulmonary contusions, aspiration, left ventricular dysfunction or failure, and inflammation due to systemic inflammation due to trauma or infection) and treatments to improve cerebral perfusion (crystalloid administration, hyperchloremic metabolic acidosis, hypernatremia, and vasopressor therapy). It is critical that the physician caring for these patients have a neuroprotective plan in place for induction and intubation, as well as adequate training and skill to obtain an artificial airway. In addition, the physician needs to be adept at ongoing neuro-resuscitation in the face of progressive lung disease and hemodynamic instability from SIRS and rising MAPs impeding cardiac preload. The initial step in treating the head-injured pediatric patient is always to promote adequate oxygenation and ventilation, and to prevent or treat hypotension thereby limiting ischemia. Criteria for tracheal intubation include hypoxemia not resolved with supplemental oxygen, apnea, hypercarbia ($PaCO_2 > 45$ mm Hg), GCS ≤8, an incremental decrease in GCS greater than 3 independent of the initial GCS (combined with clinical correlation, anisocoria greater than 1 mm, cervical spine injury compromising ventilation, loss of pharyngeal reflex, and any clinical evidence of a herniation pattern or Cushing triad).[501]

Induction and Intubation. Patients with neurologic injury are at a high risk for aspiration during induction of anesthesia, due to loss of airway protective reflexes. In addition, there is a heightened risk of cervical spine injury due to trauma and most patients will be in a cervical collar requiring manual in-line stabilization. The goal of intubation in the neurologically impaired patients should be (1) rapid sequence from induction to placement of an ETT to reduce the risk of pulmonary aspiration; (2) blunt nociceptive reflexes that may further elevate ICP or cerebral hypertension that may exacerbate intracranial hemorrhage or facilitate herniation; (3) maintaining adequate, age-appropriate CPP; and (4) limiting ischemia by maximizing adequate oxygen delivery and maintaining $PaCO_2$ in a normal range to ensure appropriate CBF.[502] It should be assumed that all patients are at risk for a full stomach and cervical spine injury, so intubation should be performed utilizing a neuroprotective, rapid-sequence induction whenever possible. Supplemental oxygen (100%) should be delivered by face mask to allow nitrogen washout from the patient's FRC to allow sufficient oxygenation prior to tracheal intubation attempts. To avoid risk of aspiration bag-valve-mask (BVM) ventilation should not be done, unless the patient has signs and symptoms of impending herniation or life threatening desaturation events. Outside of impending herniation, if BVM ventilation is conducted it is imperative to not over-ventilate the patient, decreasing $PaCO_2$ and thereby increasing cerebral vascular resistance, resulting in decreased CBF and metabolic delivery in a brain-injured patient. A separate health care professional's sole responsibility is to maintain the child's neck in a neutral position by mild axial traction during airway maneuvers to prevent or perpetuate cervical spinal injury. Cricoid pressure should be done by a third individual only if the individual is appropriately trained in the technique and it should be abandoned if it hinders a rapid intubation attempt. Orotracheal intubation by direct laryngoscopy should be performed, and nasotracheal intubation should be avoided due to potential for direct intracranial damage in a patient with a basilar skull fracture.

Because tracheal intubation is a noxious stimulus and can increase ICP, appropriate sedative and analgesic medications should be administered during rapid-sequence induction. The hemodynamic and neurologic status of the patient dictates the choice of agents. Patients usually receive lidocaine (1-1.5 mg/kg) intravenously before intubation to help blunt the rise in ICP that occurs during direct laryngoscopy.[73] For the hemodynamically unstable patient, the combination of lidocaine, etomidate (0.2-0.6 mg/kg), and neuromuscular blockade with rocuronium (1 mg/kg) or succinylcholine (1 mg/kg) IV is a popular choice. The authors believe that succinylcholine may still be an option for rapid sequence intubation (RSI) in children who may be a difficult airway due to its rapid recovery, as opposed to the non-depolarizing intermediate neuromuscular blockade of rocuronium. There are several choices for induction agents in the critically ill child with acute brain injury. In the following sections, we will discuss the pros and cons of each induction agent. It still remains unclear if any of these agents have particular advantages or disadvantages for patients with brain injury, all have been implicated in animal studies as neuroprotectants and neurotoxins. But what is clear is that they are essential to the care of these patients and practitioners should stay current with literature and consider the pharmacodynamics of each drug.

Etomidate. Etomidate is a short-acting IV drug that produces sedation, anxiolysis, and amnesia. Side effects include respiratory depression, hypotension, myoclonus, and adrenal suppression; and it should not be used in children with suspected adrenal insufficiency and sepsis.[503] Etomidate has the benefits of decreasing ICP by reductions in CBF and $CMRO_2$ and has the advantage of producing less cardiovascular depression than barbiturates or propofol, preserving CPP.[504,505] These neuroprotective qualities are counterbalanced by its ability to increase cerebral vascular resistance by a greater magnitude than its reduction of $CMRO_2$ resulting in an increased metabolic deficit.[506,507] The increased metabolic deficit has the potential expand the ischemic core and penumbra in brain injured tissue. This increase in cerebrovascular tone is thought to be attributed to etomidate's inhibition of NO synthase.[508] Particular attention should also be paid to the rapid recovery of etomidate, once the airway is secured etomidate's effects on consciousness dissipates quickly, principally due to the redistribution of the drug from the brain to inactive tissue sites. Recovery of consciousness can be between 5 and 15 minutes, and if rocuronium (paralyzed for approximately 45 minutes) is used in combination for RSI, the patient will need ongoing sedation while paralyzed. The addition of a short-acting opioid such as fentanyl may be necessary, especially if the patient has concomitant injuries, such as bone fractures. An alternative is the combination of lidocaine, fentanyl (1-4 μg/kg), and rocuronium. In the hemodynamically stable patient, either of the provided combinations with fast-acting benzodiazepine midazolam (0.05-0.2 mg/kg) can be added. In addition, the short-acting narcotic fentanyl, when used with lidocaine, can decrease the catecholamine release associated with direct laryngoscopy.[509]

Ketamine. Ketamine is a phencyclidine derivative typically formulated as a mixture of two enantiomers in a hydrochloride salt form. It possess of low pH of around 4, which can produce pain at the injection site when administered intramuscularly or intravenously. Ketamine is a NMDA antagonist, which produces increases in CBF and $CMRO_2$.[510,511] Early studies in patients with obstructed CSF pathways reported ketamine administration increase ICP with reductions in CPP.[512,513] More recent studies in adult patients with severe head injury have demonstrated improvements in CPP and minimal increases in ICP with ketamine.[514-516] One recent report of 30 intubated pediatric head injury patients observed that single doses of ketamine lowered ICP without producing decreases in blood pressure or CPP.[517] It is still unclear what ketamine's effect is on neurologic outcome in these patients or in patients where ventilation is not being tightly controlled. However, we believe that ketamine can be used in the brain injured patient, especially in multitrauma patients and if etomidate is not indicated.

Propofol. Propofol is a short-acting sedative-hypnotic IV agent that can be used to provide moderate or deep sedation. Propofol can induce a deep state of sedation rapidly, provide a short duration of effect, and have a pleasant recovery phase. Propofol is a very popular agent for sedating pediatric patients with neurologic conditions for noninvasive diagnostic imaging, such as a CT scan or MRI. Due to the fast onset and recovery following administration, repeated neurologic examinations are easy to assess such as a child with sickle cell disease who comes in with altered mental status due to a stroke. Propofol also has anticonvulsant properties and reduces ICP, which can be advantageous in sedating a patient with epilepsy or a patient with concerns for obstructive hydrocephalus due to a malfunctioning ventriculoperitoneal shunt to obtain diagnostic neuroradiologic imaging.[518] While there have been cases of propofol providing adequate sedation and successfully treating intracranial hypertension,[518,519] several pediatric traumatic brain injury case reports have reported metabolic acidosis and death in patients on prolonged (24 hours) continuous infusion of propofol.[520-524] Furthermore, a rare but potentially fatal "propofol infusion syndrome," associated with lactic acidosis, hyperlipidemia, and multiorgan system failure, was first described in pediatric patients who received prolonged (24 hours) continuous infusion and at higher dosages (>4.5 mg/kg/h).[525] Current guidelines suggest, that in the care of pediatric traumatic brain-injured patients, "continuous infusion of propofol is not recommended."[526] Adverse effects of propofol include pain at the injection site, apnea or respiratory depression, hypotension, and bradycardia, which can be detrimental in a patient at risk for brain ischemia. If used particular attention should be paid to the decrease in mean arterial blood pressure with the administration of propofol. Crystalloid bolus and vasopressor usage will likely be needed to counter act the effects of propofol to maintain proper CPP and avoid ischemic insult. Propofol does not provide any analgesia.

Dexmedetomidine. Dexmedetomidine, a centrally acting α_2-adrenergic agonist, is a recently FDA-approved agent used for short-term (<24 hours) continuous IV sedation of adults who are tracheally intubated.[527] Like propofol, it has a rapid onset and a relatively rapid elimination half-life and is administered as a loading dose followed by continuous IV infusion. One of the advantages is that it provides sedation with a lower risk of respiratory depression than many other sedative medications. There is increased interest with this agent as a sedative during noninvasive neuroradiologic imaging studies in children who are not intubated. In one study, dexmedetomidine was compared with propofol in children undergoing MRI studies.[528] While the onset of sedation and recovery time were significantly shorter in the children that received propofol, hypotension, respiratory depression and desaturation were more common compared with the children receiving dexmedetomidine.[528]

There is increased interest in the use of dexmedetomidine as a sedative and potential neuroprotective agent in both adults and children, as animal studies revealed neuroprotection from hypoxia-ischemia and decreased apoptosis, and adult human studies in healthy volunteers demonstrated parallel decrease in cerebral metabolic rate for oxygen and CBF, which may potentially be helpful in briefly sedating patients who are at risk for intracranial hypertension, such as head trauma, brain tumor, and obstructive hydrocephalus.[529] In pediatric traumatic brain injury case reports, no detrimental effects on their ICP were observed. However, systemic hypertension was observed in one child who was receiving dexmedetomidine with other sedatives, while bradycardia was observed in two other children who were receiving dexmedetomidine, other sedatives, and therapeutic hypothermia.[530,531] Further studies are warranted on the potential use of this agent in children at risk for intracranial hypertension. The most common adverse side effects of dexmedetomidine appear to be cardiovascular. Bradycardia with rare reports of sinus pause or cardiac arrest has been reported. Hypotension has been reported as well as hypertension, the latter thought to be due to peripheral α_{2B} agonism with peripheral vasoconstriction. There are conflicting reports on the effects of ventilatory function, with some studies suggesting mild respiratory depression, while others show no effect. While ICP does not appear to increase, CPP and CBF have been shown to decrease. The effects on seizure threshold appear to be mixed.[532] The authors do not recommend dexmedetomidine as an induction agent; however, it may be a useful agent for patients with brain injury and ongoing sedation needs; however, further study in pediatric patients is needed.

After successful tracheal intubation, oxygen saturation of 100%, normocarbia (35-39 mm Hg confirmed by arterial blood gas and trended with an end-tidal CO_2), and a chest x-ray showing the tracheal tube in good position above the carina (right mainstem tracheal intubation is common in pediatrics) should be confirmed. Unless the patient has signs or symptoms of herniation, prophylactic hyperventilation ($PaCO_2$ < 35 mm Hg) should be avoided. Hyperventilation causes cerebral vasoconstriction, which decreases CBF and subsequent cerebral blood volume—this will lower ICP, but may lead to ischemia.[533] However, in the presence of signs and symptoms of herniation, such as the Cushing triad (irregular respirations, bradycardia, systemic hypertension), pupillary dysfunction, lateralizing extremity weakness, or extensor posturing, hyperventilation with 100% oxygen can be a life-saving maneuver. Hyperoxia is to be avoided, once a stable airway is obtained, and FiO_2 should be titrated to maintain SaO_2 greater than 90%. Elevating the head to 30 degrees (with C-spine precautions) increases venous drainage and lowers ICP.[534,535] Furthermore, the head should be midline to prevent obstruction of venous return from the brain. If these maneuvers don't relieve the signs and symptoms of herniation, additional sedative and analgesic agents can be administered as long as hypotension is avoided.

Supraglottic Airway Devices. While supraglottic airways are not considered a permanent airway in critically ill patients, competency in placement is critical for all individuals participating in resuscitation of a brain-injured child. Supraglottic airway devices, such as a LMA device, can be lifesaving, and in a situation where there is difficulty with direct laryngoscopy and inadequate BMV, an LMA should be placed to limit hypoxia and control ventilation until a physician with advanced airway skills can arrive to place an ETT.

Postintubation Stabilization. After successful intubation, inspired oxygen should be titrated to maintain oxygen saturation greater than 90 percent, normocarbia (35-39 mm Hg confirmed by arterial blood gas and trends followed with end tidal CO_2, unless there is impending herniation when it is acceptable to use moderate hyperventilation to 30-35 mm Hg), and confirmation of ETT position with a portable chest radiograph.[533] The head of the bed should be elevated to 30 degrees, and the patient's head should remain midline to improve venous drainage and lower ICP.[534]

Neurologic Monitoring. Recent guidelines published by Kochanek et al. provide an update on treatment for infants, children, and adolescents with TBI.[536] ICP increases when the intracranial volume of one of the four compartments (CSF, blood, brain, and supporting tissues) within the cranial vault increases. An increase in one compartment can occur without raising ICP if an equal volume is displaced from another compartment. When displacement is no longer possible, ICP rises in proportion to the added volume. In older children and adults who have a rigid calvaria, the cranial cavity is a closed container and the contents are noncompressible. In patients with a GCS of 8, there is Grade III evidence to place and ICP monitor.[536] Treatment of ICP should be considered when pressure is greater than

20 mm Hg; however, absolute goals are unclear children, and intermittent increases in ICP greater than 20 mm Hg may be associated with autonomic instability. Chesnut et al. have recently reported in a randomized control trial comparing intracranial monitoring with a strategy of imaging and clinical examination in adults with severe TBI.[537] While aspects of the study and recent evidence in adult severe TBI calls into question the utility of treating an ICP goal of 20 mm Hg, these goals should likely be used as a component of multimodal monitoring (MMM). The most common monitor used in TBI as an adjuvant monitor for MMM is brain tissue oxygenation (Licox, Integra). There is limited evidence in children, but in our center brain tissue, oxygen monitoring is a standard in children with severe TBI.[484,538] If brain tissue oxygenation is used, maintain partial pressure of brain tissue oxygen greater than 10 to 15 mm Hg. It is unclear how multimodal neurologic monitoring, both invasive (brain tissue oxygenation, microdialysis, CBF, intracranial EEG) and noninvasive, should be considered for advanced neuroresuscitation, but studies including the one by Chesnut et al. prove that future research is critical to understand the mechanisms, timing, and monitoring of the brain to limit secondary injury.

Adjuvant First and Second Tiered Therapies for Intracranial Hypertension and Secondary Injury. In the 2012 guidelines[536] the use of hypertonic saline for intracranial hypertension is now grade II evidence and should be considered reduce ICP in pediatric TBI. Use of 3% saline to treat increased ICP is gaining in popularity[539] because the sodium does not cross the blood-brain barrier quickly and it has an osmolar gradient similar to that of mannitol. Three percent saline has additional theoretical beneficial effects, including enhancement of cardiac output, reduction of inflammation, restoration of normal cellular resting membrane potential and cell volume, and stimulation of the release of atrial natriuretic peptide. Recommended dosing is 6.5 to 10 mL/kg IV bolus, but the practitioner may consider starting with small boluses and titrate to pharmacodynamics response. Repeat doses can be given but it is recommended to keep serum osmolality less than 320 mOsm/L. Prophylactic hyperventilation less to a $PaCO_2$ less than 30 mm Hg should be avoided. Mannitol reduces ICP by decreasing blood viscosity and transiently increasing CBF and oxygen transport. The adenosine concentration decreases and CBF is maintained in areas that have intact autoregulation. CBF remains constant despite a decrease in cerebral blood volume and ICP. Mannitol also reduces ICP by withdrawing water from the brain parenchyma and excreting the water as urine.[540] It takes 20 to 30 minutes for this osmotic effect of the drug to develop. Intermittent boluses of 0.25 to 1 g/kg of mannitol are administered intravenously to control ICP. The drug eventually enters the CSF and can increase ICP. Barbituates should only be considered for refractory intracranial hypertension. There is no evidence to recommend tight glucose control in head injured patients, nor is there evidence suggesting the use of immune modulating diets at this time. There is grade II evidence to suggest that antiepileptic therapy should be initiated in patients with severe traumatic brain injury; in our institution, we placed continuous EEG monitoring and start prophylactic levetiracetam. Elevating the head of the bed 30 degrees while keeping it in the midline position enhances cerebral venous outflow. Even slight movement of the head to a few degrees off midline may double the ICP.

Hypothermia for Severe Traumatic Brain Injury. Hutchison et al. published a multicenter randomized control trial to investigate the use of hypothermia as a neuroprotective strategy in children.[541] This trial concluded that children with severe TBI, where therapeutic hypothermia (32.5°C for 24 hours) was initiated within 8 hours of injury, there was no improvement in neurologic outcome and the hypothermic group had an increase in mortality. Subsequent analysis of this study suggests that the hypothermia group had a significant increase in hypotension and decreased CPP that may have contributed to the increase in mortality.[542] A second phase 3 randomized control trial was initiated to compare hypothermia and normothermia after severe TBI in children with a prolonged hypothermia window, 48 to 72 hours, and slower rewarming phase.[543] The study was terminated early for futility after interim analysis. Therefore, we believe current standard of care is normothermia for traumatic brain injury in children.

Decompressive Craniectomy. Decompressive craniectomy with duraplasty may be considered for pediatric patients with TBI who display early signs of deterioration, herniation, or refractory hypertension. Currently, there is an ongoing study in adults to investigate surgical decompression for severe TBI.

Environment. Care of patients with TBI within an organized trauma system has shown to reduce mortality associate with severe injury.[544] Unfortunately, most severe traumatic brain injuries occur in regions lacking in prehospital and advanced care in an ICU.[545] Critically injured children with traumatic brain injury should be stabilized and transferred to a level 1 trauma center as soon as possible.

Hypoxic-Ischemic Encephalopathy

There is little evidence that increased ICP or correction of ICP alters the outcome of patients with HIE. The clinical impression is that the outcome is less favorable in patients who have trauma or metabolic encephalopathy and that aggressive management of ICP, at best, prevents further CNS damage, which is important.[546] The GCS score provides a reasonable assessment of neurologic function in these patients.

Hydrocephalus

Another cause of increased ICP is an increase in CSF volume (i.e., hydrocephalus). Common causes of hydrocephalus include obstructed ventricular shunts, aqueductal stenosis/compression as a result of congenital malformations, infection, posterior fossa tumors, or intracranial bleeding. Inserting an external or internal shunt to reduce the volume of CSF can be lifesaving.

Tumors

Brain tumors are common in children, and approximately 70% occur in the posterior fossa. The most common tumor type is astrocytoma. The initial symptoms may include focal deficits, ataxia, or symptoms of increased ICP. A change in condition following tumor resection requires an immediate neurologic evaluation and possibly a brain CT scan. Following a posterior fossa craniectomy, hemorrhage into the posterior fossa can compromise respiration, and if there is an externalized ventricular drain present, output should be carefully inspected. Postoperatively, the patient should be followed closely for syndrome of inappropriate antidiuretic hormone secretion (SIADH), DI, and cerebral salt wasting. SIADH usually occurs within 24 to 48 hours following surgery and results in the retention of free water and a decrease in serum electrolytes, which may rapidly worsen cerebral edema. Central DI usually follows the removal of a suprasellar tumor and results in significant diuresis when antidiuretic stores are exhausted with a resulting increased serum osmolality and a low urine osmolality and urine specific gravity (<1.005). DI is part of a typical triphasic (SIADH to DI to SIADH) response following suprasellar surgery and is treated with volume replacement, and a vasopressin infusion may be required.

Status Epilepticus in Children

Status epilepticus is a continuous motor seizure that lasts for more than 20 minutes or a series of seizures without intercurrent awakening. Although it is common for physicians to never find a cause of the seizures, the most commonly diagnosed causes are infections (meningitis or encephalitis) and metabolic abnormalities (toxins, head trauma, and hypoxic and ischemic injury). Because seizure activity increases with status epilepticus, brain and skeletal muscle metabolism and oxygen consumption increase and place the child at risk for cellular hypoxia. During a seizure, airway obstruction and ineffective chest wall and diaphragmatic excursion can limit ventilation and worsen arterial hypoxemia and hypercapnia. Treatment of a seizure begins with establishing a patent airway, administering oxygen, and ensuring adequate ventilation. IV anticonvulsant drugs are given to stop the seizure. Commonly used anticonvulsants include lorazepam, phenobarbital, paraldehyde, and phenytoin. Lorazepam is a rapid and reliable drug used to stop seizures. Boluses of 0.1 mg/kg are given intravenously or rectally when there is no IV access. Phenobarbital, 5- to 10- mg/kg boluses (maximal dose of 20 mg/kg), also stops seizures. The main complication of lorazepam is respiratory depression when administered in high doses. Giving both phenobarbital and lorazepam together exaggerates the respiratory depression. Fosphenytoin is also given intravenously in doses of up to 20 mg/kg and should be administered slowly to avoid cardiovascular depression. Paraldehyde, 0.3 mL/kg, can be given rectally. Finally, an IV injection of 1 to 4 mg/kg of sodium thiopental stops most intractable seizures; higher doses of the drug may cause apnea, and the risk of vomiting and aspiration of gastric contents is real. Once the seizures are under control, the cause of the seizures must be determined.

Renal System

Functional Development of the Renal System. Embryologic development of the renal system begins in the middle of the third week of gestation with development of the pronephric tubules. By 10 weeks' gestation, a functioning kidney and collection system exist, and fetal urine is discharged into the bladder. At 32 to 36 weeks' gestation, each kidney has a full complement of nephrons. Because the placenta is the major excretory organ of the fetus, renal growth is not governed by functional requirements. Renal growth increases linearly with body weight and body surface area during the third trimester of pregnancy. The glomerular filtration rate (GFR) increases rapidly from 28 to 35 weeks of gestation. At term, the GFR is 10 mL/min/m^2 and increases to 20 mL/min/m^2 by 2 weeks of age. Although the GFR of premature infants is lower, the rate of increase is the same as that in a term infant.[547] Tubular function is not fully mature in full-term newborns. The newborn kidney is sensitive to antidiuretic hormone (ADH) and vasopressin, and urine osmolarity can vary from only 50 up to 780 mOsm/L.[548] The tubular function of premature infants is less mature.

The newborn's renal threshold for bicarbonate is about 20 mEq/L, which means that standard acid-base nomograms do not apply to infants because their serum bicarbonate concentration of 20 mEq/L is not indicative of metabolic acidosis. The renal tubular glucose threshold of term infants is similar to that of adults, but it is only 125 to 150 mg/dL in premature infants. A full-term infant has 1% or less fractional excretion of sodium by the third day of life. Fractional excretion of sodium can be much higher (5%) in premature infants. Renin, angiotensin, and aldosterone concentrations are high in newborns and decrease over the first few weeks of life.

Assessment of Renal Function. In the resting state, the kidney receives 20% to 25% of the cardiac output, and due to autoregulation, the kidney maintains near constant renal blood flow and GFR. Creatinine is an end product of skeletal muscle catabolism and is excreted solely by the kidneys and blood urea nitrogen is a byproduct of protein metabolism. Values for BUN can increase independent of renal function as a result of dehydration, high protein intake, and degradation of blood from the GI tract. Normal values for pediatric renal function are presented in Table 79.10.

Renal Pharmacology. An important aspect of critical care is the maintenance of appropriate fluid balance in the critically ill child. Even in patients who have normal renal function, such as patients with ARDS, chronic lung disease, and CHF, diuretics are often used to limit lung edema and help with cardiorespiratory dysfunction. The ascending loop diuretic furosemide is likely one of the most widely used drugs in pediatric intensive care. Furosemide reaches the ascending loop of Henle by the way of the tubular fluid. A prescribed starting dose of furosemide is typically 0.5 to 1 mg/kg up to approximately 10 mg total dose for patients who are naïve to diuretic therapy. The lowest dose necessary to increase urine output should be used, to limit

TABLE 79.10 Normal Values for Pediatric Renal Function

	Age	Value
Creatinine (mg/dL)	1 year	0.41 ± 0.1
	10 years	0.61 ± 0.22
	18 years	0.91 ± 0.17
Glomerular filtration rate (mL/min/1.72 m^2)	2-8 days	39 (range, 17-60)
	6-12 months	103 (range, 49-157)
	2-12 years	127 (range, 89-165)
Urine concentration (mOsm/L)	1 month	600-1100
	2-16 years	1089 (range, 870-1309)

Modified from Goldsmith DI. Clinical and laboratory evaluation of renal function. In: Edelman CM Jr, ed. *Pediatric Kidney Disease*. Boston: Little, Brown; 1978:213.

toxicity including electrolyte imbalance and ototoxicity.[549] With progressive renal dysfunction, escalating doses of furosemide may be required to maintain the same clinical response. Electrolyte and renal function need to be monitored frequently, as diuretic therapy frequently causes significant hypokalemia and hypochloremia, as well as other electrolyte wasting. Furosemide is albumin-bound and, in low albumin states, often found in critical illness, the delivery of furosemide to renal secretory sites is decreased. Improved delivery and diuresis is often improved with the administration of 25% albumin just before or with the diuretic. The typical dose is 0.5 to 1 g albumin/kg. Additional diuretics acting at other locations such as hydrochlorothiazide (distal tubule) can are often used as adjuvant medications to improve diuresis. The drug spironolactone, which blocks the hormone aldosterone, is a weak diuretic but may prevent spare potassium loss. Failure of increasing amounts of diuretics to be effective likely represents worsening renal perfusion and or renal failure.

Renal Failure. Acute renal failure is defined as an abrupt, often temporary loss of renal function (see Chapters 17 and 42), where there is insufficient removal of nitrogenous wastes and problems with fluid and electrolyte balance. Acute renal failure is described by (1) the area of obstruction (prerenal, postrenal [obstructive], or intrinsic renal disorders); and (2) the urine volume (oliguria, polyuria, and anuria). Urine composition is often altered, and fluid, electrolyte, and acid-base disorders are common in acute renal failure. Common causes include hypoperfusion, obstruction, toxins, drugs, inflammation, and autoimmune disorders.

Prerenal causes are common in the critically ill child due to systemic hypoperfusion and reduced renal blood flow, resulting in reduced urine output and results in azotemia and ischemic renal damage. *Azotemia* is the term for the accumulation of nitrogenous byproducts of protein metabolism. Intravascular fluids in the case of dehydration or fluids and inotropic support may be needed to reverse prerenal renal failure. The adequacy of circulating blood volume is assessed by CVP and cardiac output measurements, and by estimating renal blood flow with Doppler flow studies or nuclear imaging techniques.

Intrinsic renal failure is caused by disorders of the renal glomeruli, tubules, or blood vessels. Glomerular diseases include hemolytic-uremic syndrome (HUS), poststreptococcal glomerulonephritis, Henoch-Schönlein purpura, and other inflammatory and immune complex diseases. Acute tubular injury is most commonly caused by hypoxia and ischemia; other causes are rhabdomyolysis, sepsis, hyperthermia, hemolysis, and a myriad of nephrotoxins, including mercury, carbon tetrachloride, and ethylene glycol.

Postrenal obstruction of urine flow can occur anywhere within the collecting system, but it occurs most commonly as partial obstruction of the bladder neck or the ureterovesical or ureteropelvic junction. All these malformations cause obstructive nephropathy and renal injury or renal failure. Signs of obstruction may be subtle and require radiologic, ultrasonic, or endoscopic evaluation to detect. Recurrent urinary tract infections are frequent clinical manifestations of obstructive lesions.[550]

Vascular diseases, including arterial embolism, venous thrombosis, and congenital malformations, are also causes of acute renal failure.

Hyperkalemia and Abnormalities of Sodium. With increasing renal dysfunction there is a continued decrease in excretion of potassium. Hyperkalemia can lead to life-threatening cardiac arrhythmias and requires immediate treatment. ECG presentation of results in a peak in the T wave at moderately elevated potassium levels. As hyperkalemia increases, there may be ST segment depression, and widening of the QRS complex, leading to conduction abnormalities, bradycardia, ventricular fibrillations or asystole. Treatment includes removal of exogenous potassium (administration should be discontinued immediately) and calcium in the form of IV CaCl 10 to 20 mg/kg or CaGluconate 30 to 60 mg/kg to stabilize the cardiac cell membrane. IV sodium bicarbonate 1 to 2 mEq/kg will drive potassium into the intracellular fluid by increasing blood pH. Glucose and insulin also drive K+ into cells. Glucose is given as 1 to 2 g/kg IV with insulin 1 unit per 4 g of glucose IV. If the patient is intubated, increasing RR makes blood more basic driving K+ into the cells. It is important to note that none of these efforts will remove potassium from the body. Prior to the initiation of dialysis, potassium removal may be attempted with the ion exchange resin Kayexalate, a sodium polystyrene sulfate, which can bind potassium. It is given orally or rectally in suspension but does require excretion from the body. The dose is 1 g/kg orally, and it can be given every 6 hours; rectally, it can be given every 2 to 6 hours. The enema route is less effective than oral administration.

Severe hyponatremia and hypernatremia can be another electrolyte disturbance seen in the critically ill child. Hyponatremia may present with seizure activity, often when serum sodium is less than 120 mEq/L. In the presence of hyponatremic seizures, the initial treatment is the administration of 3% hypertonic saline with a goal to terminate seizure activity and raise serum sodium to greater than 124 mEq/L. However, in the absence of seizures, if a patient reached this low value slowly, it has to be corrected slowly, to potentially avoid osmotic demyelination. The same condition applies to hypernatremia. Rapid correction of elevated serum sodium is likely more harmful than the value itself.

BOX 79.4 Indications for Dialysis

1. Severe hyperkalemia
2. Metabolic acidosis unresponsive to therapy
3. Fluid overload with or without severe hypertension
4. Fluid overload with or without congestive heart failure
5. Uremia causing encephalopathy, pericarditis, or bleeding
6. Nonobstructive anuria
7. Inborn errors of metabolism
8. Certain drug overdoses
9. Significantly elevated (>100) blood urea nitrogen possibly a relative indication
10. Potential treatment can reduce inflammation with sepsis or systemic inflammatory response syndrome

Renal Replacement Therapy. Renal replacement therapy may be required to improve ongoing fluid shifts and significant electrolyte disturbance (Box 79.4). Modalities for renal replacement therapy are commonly: peritoneal dialysis, hemodialysis, or continuous venovenous dialysis. Modality often depends on the size of the patient and the experience and resources of the institution.

Peritoneal dialysis (PD) has the benefits of being relatively low-cost, causing less hemodynamic compromise compared with venovenous filtration, requires no central venous line, and is technically simpler. This technique is especially effective in infants and smaller children. Peritoneal dialysis requires the insertion of a soft, multiholed catheter into the peritoneal cavity. When patency of the catheter is confirmed, a dialysate solution is infused that equilibrates with plasma and extracellular fluids. The parietal and visceral surfaces function as semipermeable dialysis membranes. The composition of the dialysis fluid is similar to that of plasma and consists of approximately 130 mEq/L of sodium, 100 mEq/L of chloride, 35 mEq/L of acetate or lactate as a buffer, 3.5 mEq/L of calcium, and 1.5 mEq/L of magnesium. The glucose concentration of the solution can be either isosmotic or hyperosmotic. Hyperosmotic solutions remove fluid and electrolytes. Respiratory compromise may occur with peritoneal dialysis because the increased abdominal pressure caused by the dialysate in the abdomen may prevent effective spontaneous ventilation. Mechanical ventilation will be required if this occurs. Bacterial or fungal peritonitis is common. Severe dehydration, circulatory collapse, and metabolic derangements are other complications of peritoneal dialysis.

The principles of hemodialysis are essentially the same as those of peritoneal dialysis, except the blood interfaces with a semipermeable membrane rather than with the peritoneum. Hemodialysis is more appropriate in the acute setting with life-threatening electrolyte disturbances, fluid overload, and toxic ingestions. Hemodialysis is more efficient than peritoneal dialysis. Hemofiltration and ultrafiltration are processes of convective solute transport. An ultrafiltrate of plasma is created by hydrostatic pressure exerted across a highly permeable membrane, with simultaneous blood volume replacement with a modified lactated Ringer solution.[551] Continuous venovenous hemofiltration (CVVHF) is a common form CRRT, which provides isotonic fluid removal but minimal solute clearance. However, these circuits can be easily converted to perform dialysis, termed *continuous venovenous hemodialysis* (*CVVHD*), providing more solute clearance. In smaller patients, accurate flow rates are important in circumstances where more than 15% of the patient's circulating blood volume can be in the CVVHD tubing. Furthermore, technical challenges occur in smaller patients due to flow characteristics of smaller dialysis catheters. Hemodialysis can be performed with two separate 5 Fr single lumen catheters, but typically a dual-lumen 7 Fr catheter at a minimum is required. Anticoagulation for CVVHD can be either with heparin or with regional citrate administration. Citrate can be given in a stopcock prior to the machine, which creates a regional area of hypocalcium in the circuit, leading to relative anticoagulation in the circuit, while IV calcium is given back to the patient via a central line. The use of regional anticoagulation with citrate avoids the concerns of systemic anticoagulation and may reduce the risk of systemic bleeding.

Renal Failure Outcomes. The prognosis with acute renal failure depends on the patient's age, underlying disease, and the extent of the precipitating insult (also see Chapter 17 and 42). In general, children do better than adults; in fact, children usually recover completely from a renal insult if the hypoxia or ischemia lasted only a short time and other organ systems are not involved. Children with chronic renal failure require long-term outpatient peritoneal dialysis or hemodialysis until they can undergo renal transplantation.[552] It has been demonstrated that the degree of fluid overload at initiation of CRRT is associated with patient mortality.[132] This has been found to be independent of patient severity of illness scoring.

Hemolytic-Uremic Syndrome. HUS is one of the most common causes of acute renal failure in children. This syndrome is characterized by microangiopathic hemolytic anemia, thrombocytopenia, and acute renal injury. In North America, HUS is most often associated with infection by cytotoxin-producing *Escherichia coli* O157, but other serotypes and other Shiga-like toxin–producing bacteria have been implicated.[553] *E. coli* O157 resides in the intestinal tract of cattle and may contaminate beef during processing.[554] The organism is killed by cooking. Infections can be spread by person-to-person contact in daycare centers, institutions, and the military. There is also a familial form of the disease that accounts for a small percentage of the total cases. HUS is seen predominately in 0.5- to 4-year-old children, but it can occur in all age groups.[190] It shares many laboratory and clinical features with the adult disease, thrombotic thrombocytopenic purpura. In fact, some investigators consider the two disorders a continuum of the same disease. The abnormalities that develop in HUS are believed to be caused by cytotoxins and lipopolysaccharide, a bacterial endotoxin. Toxin-induced damage to renal endothelial cells, the vasculature, and other organs is directly or indirectly associated with the activation of leukocytes.[555] Cytokines such as interleukin-1 and tumor necrosis factor, prostaglandin I_2, thromboxane A_2, and von Willebrand factor multimers probably play a role in the pathogenesis of this disease.[556] The time from exposure to the organism to initial evaluation of the patient varies from 3 to 12 days. Symptoms last for about a week. Patients usually have abdominal cramping, bloody diarrhea, tenesmus, and vomiting.[557] On average, about 10% of children with *E. coli* O157–induced bloody diarrhea progress to HUS. Mildly affected patients exhibit anemia, thrombocytopenia, azotemia, and decreased urine output, and have an uncomplicated course. In severely affected patients, anuria is common, hypertension and seizures may occur, and the duration of illness is prolonged. A small number of children exhibit progressive and permanent renal insufficiency, severe and recurrent hemolysis, thrombocytopenia, and neurologic impairment. Hematologic abnormalities include hemolysis and thrombocytopenia. Hemolysis often causes hyperbilirubinemia and, despite reticulocytosis, severe anemia with hemoglobin concentrations of 4 to 5 g/dL. Thrombocytopenia is the result of platelet destruction and sequestration in the liver and spleen.[558] The remaining platelets show evidence of impaired aggregation.[559] Disseminated intravascular coagulation (DIC) is relatively common. Glomerular capillary endothelial injury is the most consistent renal finding in HUS. Acute renal failure with oliguria or anuria usually lasts less than a week but may linger for more than 10 weeks.[560] Glomerular or arterial injury, or both, may predominate, depending on the presence and extent of renal insufficiency (glomerular injury) and hemolysis and hypertension (arterial injury). CNS abnormalities are manifested as decreased levels of consciousness, seizures, irritability, ataxia, hypotonia, hemiparesis, hyperreflexia, and hallucinations; these problems may be caused by severe hypertension, electrolyte disturbances, microthrombi, or cerebral edema and increased ICP.[561] Abdominal cramping is common and may be difficult to distinguish from intussusception, intestinal stricture or bowel perforation, colonic gangrene, or other surgical emergencies.[562] Pancreatitis is common in patients with HUS. CHF may occur if there is fluid overload, hypertension, anemia, or myocardial depression caused by circulating endotoxins. Treatment of HUS is primarily supportive. Meticulous attention should be paid to volume status, electrolyte and acid-base balance, nutrition, antisepsis, and treatment of hypertension and coagulopathies. Enteric isolation is mandatory to prevent secondary spread of the disease. Accurate fluid intake and output measurements and frequent assessment of weight and volume status are important for management of these patients. A central venous catheter is useful for CVP measurements, blood sampling, and administration of IV medications and nutrition. Nephrotoxic drugs should be avoided if possible. If nephrotoxic drugs must be given, the drug dose should be adjusted and serum concentrations monitored closely. Daily fluids should be restricted to the amounts required to replace insensible losses, urine output, and other ongoing losses. Fluids administered should reflect the electrolyte content of the fluid losses. Caloric support is essential. Enteral feedings are preferred, but parenteral feeding may be necessary if ileus develops. Antidiarrheal medications prolong the duration of colitis, and antibiotics may increase the risk for HUS.[563,564] No specific treatment has been effective to date. Heparin, fibrinolytic agents, aspirin, dipyridamole, corticosteroids, vitamin E, and furosemide have not affected the outcome of HUS.[201] Immunoglobulin therapy, plasmapheresis, and infusions of fresh frozen plasma have had mixed results, but no long-term therapeutic benefit has been demonstrated. Dialysis, improved nutrition, and supportive care have decreased the mortality rate from 100% in the original report to less than 10% in the last 30 years. Mortality rates remain high in developing countries and in children with a genetic predisposition for HUS.

ENDOCRINE SYSTEM

Adrenal Axis

Abnormalities of the adrenal axis result in deficient or excessive production of glucocorticoids, mineralocorticoids, or both. Many of these disorders are diagnosed and treated as they are in adults. Congenital adrenal hyperplasia, pheochromocytoma, and iatrogenic chronic adrenal insufficiency will be discussed briefly.

Congenital Adrenal Hyperplasia

Congenital adrenal hyperplasia is an autosomal recessive disorder that is associated with deficiencies in either 21-, 11-, or 17-hydroxylase. 21-Hydroxylase deficiency in children can be partial (simple virilizing form) or more complete (salt-losing form); at birth, affected children demonstrate masculinization of the external genitalia, and those with the more complete deficiency show a progressive salt-losing state (i.e., loss of sodium and elevation of potassium). This condition is usually manifested in the first few weeks of life as feeding difficulty, vomiting, and failure to thrive. The clinical and historical course is suggestive of pyloric stenosis. If the deficiency is not diagnosed and treated early in life, affected children may suffer severe cardiovascular collapse. A blood sample should be obtained for electrolytes, glucose, and if the diagnosis has not been established, adrenocorticotropic hormone (ACTH), cortisol, aldosterone, and plasma renin activity.

Treatment requires aggressive support of intravascular volume and myocardial function, glucose, and replacement of the deficient hormones. Cortisol can be replaced by oral administration of hydrocortisone at a dose of 25 mg/m^2/day divided into three doses; if the child cannot tolerate oral medication, cortisone acetate can be administered intramuscularly at a dose of 37.5 mg/m^2/day once every 3 days. For emergency therapy, when the oral route is not possible and perfusion of the muscle is poor, hydrocortisone acetate is used intravenously at a bolus dose of 1.5 to 2.0 mg/kg and then 25 to 250 mg/day in divided doses. Mineralocorticoid is replaced with cortisone acetate, 0.05 to 0.2 mg/day orally; these patients usually require the addition of salt to their diet. Deficiencies of 11- and 17-hydroxylase do not result in salt wasting; masculinization and hypertension are the common initial signs

Pheochromocytoma

Less than 5% of pheochromocytomas are diagnosed in childhood. As a rule, these tumors are confined to the adrenal medulla, but they can occur anywhere throughout the sympathetic chain. The clinical signs and symptoms of excessive catecholamines are the same as those in adults. Pre-, intra-, and postoperative therapy is similar to adults.

Iatrogenic Chronic Adrenal Insufficiency

Long-term daily use of steroids for the treatment of asthma, nephrotic syndrome, and malignancies is common. Such use may cause a hypoadrenal state and increase the risk for cardiovascular collapse during a severe illness or stress. In children, topical steroids can also depress the production of ACTH. Replacement of stress-level steroids (three times the daily replacement dose) is required.

Anterior Pituitary

Panhypopituitarism is usually secondary to a tumor or to aggressive dissection of a tumor.[565] Acute ICU problems related to this lesion include support of the adrenal axis and abnormalities of ADH.

Diabetes Insipidus

DI can be of central, renal, or psychogenic origin. The central mechanism is the most common form in ICU patients. Absence of ADH results in polyuria and polydipsia; patients with a severe form of this disease may not be able to drink sufficiently to meet their requirement, and severe hypovolemia may develop. DI is precipitated by brain tumors, head trauma, neurosurgery, and clinical brain death.[566,567] Treatment, in the setting of the ICU, is fluid replacement or, if unwieldy, hormone replacement with aqueous vasopressin (Pitressin), 0.1 to 1.0 mL intramuscularly (duration, 4-6 hours); Pitressin tannate in oil, 0.25 to 1.0 mL intramuscularly (duration, 24-72 hours); or desmopressin acetate intranasal, 2.5 to 10 μg twice daily (duration, 10-11 hours). The clinical syndrome may be transient or chronic. In either case, close supervision of fluid intake and output is essential.

Syndrome of Inappropriate Secretion of Antidiuretic Hormone

The syndrome of inappropriate ADH secretion is associated with hyponatremia and hypo-osmolality caused by inappropriate urinary loss of sodium and free water in patients with normal kidneys. Urine osmolality is greater than serum osmolality. This syndrome is precipitated by a number of mechanisms, including head trauma, neurosurgery, meningitis, hypoxia, and any major surgical procedure in which there is large-volume fluid shifts and fluid replacement.[209,568] This disease is usually self-limited, and the only real problem occurs if the diagnosis is not considered and the level of hyponatremia is low enough to cause CNS dysfunction. Seizures are rare unless serum sodium is less than 120 mEq/dL. Care should be taken to raise the serum concentration of sodium slowly. This syndrome is treated by fluid restriction and, in severe cases, by the infusion of hypertonic or isotonic saline.

Pancreas/Insulin

Hypoglycemia. Hypoglycemia is a common problem in ICU patients. What constitutes hypoglycemia in children has been disputed. However, it is uncommon to find a blood glucose level below 40 mg/dL in normal, nourished premature, or term neonates. The usual symptoms of hypoglycemia include tachycardia, diaphoresis, weakness, mental clouding, seizures, and coma. The causes of hypoglycemia can be subdivided into disorders of increased utilization and disorders of decreased production. Transient hypoglycemia of the newborn is caused by decreased or immature hepatic gluconeogenesis and it self-corrects within hours to days. If the hypoglycemia persists, hepatic enzyme deficiencies, endocrine problems, or hyperinsulinism (i.e., pancreatic cell abnormalities, infants of diabetic mothers) must be considered. Other causes of hypoglycemia in the neonatal period include sepsis, hypothermia, hypoxia, and transplacental exposure to maternal hypoglycemic drugs. In older children, hypoglycemia is associated with ketotic hypoglycemia,[569] hepatic enzyme abnormalities, hyperinsulinism, hepatic failure, and Reye syndrome, and it is a side effect of certain drugs. Regardless of cause, the initial treatment of hypoglycemia is glucose administration. The initial dose is 0.5 g/kg given as 50% dextrose in water ($D_{50}W$). This dose should be followed by an infusion of dextrose that is sufficient to meet the metabolic requirements of the child (see the later section on the GI system).

Hyperglycemia. Hyperglycemia in the pediatric ICU can be separated into two main categories with distinct concerns and outcomes. Patients with Type I diabetes mellitus are often admitted to the ICU, with either initial presentation of the disease or those patients with known diabetes who are exhibiting recurrent problems of insulin balance. The second category of patients with hyperglycemia in critically ill children are those who develop elevated glucose during treatment for their underlying disease process, likely due to stress biology.

Diabetic Ketoacidosis. The most serious acute complication of diabetes mellitus is DKA, a syndrome of glucose and ketone overproduction and underutilization that causes hyperglycemic ketoacidosis. The clinical syndrome includes dehydration and hypovolemic shock from hyperglycemic osmotic diuresis, compensatory hyperventilation (Kussmaul pattern), life-threatening electrolyte depletion, and in cases of severe metabolic imbalance, neurologic obtundation and coma.[570] Laboratory evaluation demonstrates elevated blood glucose concentrations, severe metabolic acidosis, and compensatory hypocapnia, increased osmolality, hyperlipidemia, and a normal or low sodium level (usually fictitiously low because of the hyperlipidemia). Total-body depletion of potassium and possibly phosphate occurs. Levels of both may be falsely normal because of the metabolic acidosis.

Treatment of DKA requires careful correction of the metabolic derangements with meticulous monitoring of the multisystem complications of DKA, as well as the complications of therapy. Adequate intravascular volume is restored with an isotonic glucose-free solution, combined with exogenous insulin administration, commonly referred to as a "two-bag system."[571] Regular insulin is given as an IV infusion of 0.1 Units/kg/h. The goal is to decrease blood glucose by 75 to 100 mg/dL/h. This infusion is continued until the blood glucose reaches 250 to 300 mg/dL, at which time 5% dextrose in normal saline (D_5NS) is added to the infusate. This regimen of simultaneous glucose and insulin infusion can be continued until the patient can tolerate oral feedings and routine subcutaneous insulin administration. Most clinicians continue the insulin infusion until the acidosis is nearly corrected. Potassium concentrations should be monitored closely. These children have total-body potassium depletion, but potassium should not be added to any infusion until there is urine output. The need for phosphate may be more theoretical than real, but in most situations, half the potassium is given as a phosphate salt. The severe metabolic acidosis is usually corrected with volume and insulin administration. The use of bicarbonate to correct acidosis is generally avoided because bicarbonate may precipitate or worsen the child's neurologic dysfunction. In severe DKA, the intracellular volume of brain cells is reduced by hyperosmolar dehydration. In an attempt to maintain their normal size, brain cells generate osmotically active idiogenic osmoles (e.g., inositol) that attract more water into the intracellular compartment. As systemic rehydration and correction of the hyperosmolar state begin, the brain cells may swell until the idiogenic osmoles are metabolized or cleared. Consequently, rapid correction of osmolarity can cause significant brain edema[572] and may also worsen the neurologic dysfunction, which may require invasive neuromonitoring.[546] The pH of the brain is determined by the CSF bicarbonate level and by the CO_2content; the CSF CO_2content equilibrates much more rapidly with the vascular space than bicarbonate does. Therefore, correcting the systemic acidosis decreases the level of hyperventilation and causes a rise in $PaCO_2$; if this rise is precipitous, the CSF acidosis could worsen before the bicarbonate equilibrates with CSF. Because rapid correction of pH is problematic, bicarbonate administration is not advocated in DKA unless cardiovascular instability is present. Even then, the doses administered are small. Unfortunately, despite very careful and slow correction of the hyperosmolar and acidotic state, hyperosmolar coma and fulminant brain edema can occur.[573] The pathophysiology of brain swelling in DKA is poorly understood. Subclinical brain swelling may be relatively common in children with DKA.[574] If the swelling is significant, mannitol should be administered immediately and therapy for intracranial hypertension begun. The goal is to prevent secondary injury to the brain.

GASTROINTESTINAL SYSTEM

GI problems in the ICU include organ dysfunction and failure from acquired disease and from congenital anatomic malformations and dysfunction. Delivery of adequate nutrition to critically ill patients is necessary.

Structural and Functional Development of the Intestine

Knowledge of fetal midgut development makes it easier to understand a number of severe congenital anomalies. Although the intestine begins as a hollow tube, it is occluded by 7 to 10 weeks' gestation by rapidly growing epithelial cells. The lumen is later reconstituted when vacuoles within the epithelial cells coalesce. Some of the neonatal intestinal atresias are the result of abnormalities of this recanalization process. At 3 to 10 weeks' gestation, the midgut lies outside the abdominal cavity, with only the hindgut fixed in the left side of the abdomen. The gut rotates 270 degrees counterclockwise and reenters the abdominal cavity at 10 weeks' gestation. If the midgut fails to migrate back into the abdominal cavity, an omphalocele occurs. Abnormalities in midgut rotation result in abnormal intraabdominal relationships, the most important being malrotation and volvulus of the intestine.

Development of the Liver

The liver begins as an outgrowth of the foregut at approximately 3 weeks' gestation. During fetal life, it is relatively large in comparison to the adult liver. Although the fetus relies on the maternal liver and placenta for detoxification and excretory function in utero, the fetal liver is necessary for both prenatal and postnatal survival. As early as 10 to 12 weeks' gestation, the fetal liver is involved in glucose regulation, protein synthesis, and lipid synthesis, and is capable of some drug metabolism. The fetal liver contains approximately three times the amount of glycogen as the adult liver, but the glycogen is nearly completely released within hours of birth to compensate for interruption of the placental supply of nutrients.[575] It takes several weeks for the newborn to reestablish the store of liver glycogen, putting the infant at risk for hypoglycemia during this vulnerable period.

Congenital Malformations

Gross anatomic malformations are usually diagnosed during the first few days of life. Some, such as omphalocele, gastroschisis, diaphragmatic hernia, and imperforate anus, are apparent on the initial physical examination. Others manifest themselves in the first few days of life as failure to feed enterally, intestinal atresia, microcolon, tracheoesophageal fistula, and meconium ileus. Other malformations present difficult diagnostic and therapeutic dilemmas after the neonatal period. Specific clinical problems are discussed in the following sections.

Intestinal Malrotation and Midgut Volvulus. Malrotation of the intestine is caused by incomplete rotation of the fetal midgut when the gut migrates into the abdominal cavity. This abnormal rotation can cause partial or complete duodenal obstruction by peritoneal (Ladd) bands or, more importantly, midgut volvulus. The midgut (duodenum to transverse colon) and its vascular supply hang on a single pedicle; if the pedicle twists, the entire midgut may infarct. Infants with omphalocele almost invariably have associated malrotation of the gut. Symptomatic infants and children have signs of high intestinal obstruction (bilious vomiting) or signs of an acute abdomen, intestinal perforation, and sepsis. Treatment is surgical reduction and fixation of the volvulus and resection of nonviable bowel. Postoperative respiratory support and total parenteral nutrition are often necessary in infants who were severely compromised before surgery.

Meckel Diverticulum. Meckel diverticulum represents persistence of the omphalomesenteric or vitelline duct and is brought to the attention of the physician because of painless lower GI bleeding. The bleeding site is due to ulceration of the bowel mucosa caused by secretion of gastric acid.

Although usually self-limited, massive and life-threatening hemorrhage has been reported.[576] The diagnosis can be difficult to make because it is often one of exclusion. The technetium pertechnetate isotope scan demonstrates gastric mucosa in the diverticulum. Therapy is supportive, but particular attention must be paid to blood replacement. Definitive therapy is surgical resection.

Hirschsprung Disease. Hirschsprung disease (congenital aganglionic megacolon) is characterized by the absence of parasympathetic ganglion cells in the rectum and colon and occasionally in the small bowel.[218] Lack of ganglia cause narrowing of the distal bowel and distention of the normal proximal bowel. The clinical symptoms can be relatively minor, with abdominal distention and stool retention, or severe, with toxic megacolon, peritonitis, and intestinal perforation. Toxic megacolon is usually manifested in younger children; reported mortality rates are as high as 75% with toxic megacolon. The diagnosis of Hirschsprung disease is occasionally made by the history and physical examination. A barium enema reveals a narrowed segment with ballooning of the proximal part of the bowel. The definitive diagnosis is made by finding no ganglion cells on rectal or colon biopsy (or both). Treatment of toxic megacolon is both supportive (volume re-expansion and antibiotic administration) and definitive (surgical decompression via colostomy).

Other Intestinal Disorders. Intestinal disorders can cause bleeding, obstruction, or inflammation, and there can be secondary problems such as malabsorption and bowel perforation. GI bleeding in children is caused by inflammatory diseases (gastritis), ulcers, varices, or vascular malformations. Although ulcer disease is an uncommon initial complaint in pediatric patients, stress gastritis or stress ulcers occur in critically ill children. Prophylactic antacids or an H_2 antagonist should be considered. Bowel obstruction can be caused by intussusception, twisting of the bowel around congenital or postsurgical bands, and twisting of the bowel on itself (volvulus). Intussusception is relatively common in the pediatric age group and usually occurs in the distal part of the ileum. In only a few cases can a leading point, such as a polyp or localized edema (as seen in Henoch-Schönlein purpura), be identified. Treatment of intussusception can be surgical or, in patients with no evidence of necrotic bowel, with barium, air, or saline enema.[577] Inflammatory bowel diseases include Crohn disease and regional enteritis.[578] Infectious agents to be considered include *Salmonella*, *Shigella*, and *Yersinia*. These patients often have diarrhea, malabsorption (especially lactose intolerance), and bloody diarrhea. They also can have a toxic acute abdomen.

Necrotizing Enterocolitis. Necrotizing enterocolitis (NEC) is an often fulminant neonatal disease characterized by ulceration and necrosis of the small bowel and colon. Its cause is unknown but is probably multifactorial. Prematurity is the greatest risk factor for NEC. It is probably due to a combination of intestinal ischemia, oral feeding, and pathogenic organisms. Umbilical artery catheters, perinatal asphyxia, RDS, and persistent patent ductus arteriosus have all been implicated.[579] The incidence of NEC is on the rise, with 1% to 5% of infants in neonatal ICUs affected. The most common initial signs are feeding intolerance, abdominal distention, and bloody stools. Intestinal obstruction, bowel perforation, and sepsis may follow. Treatment consists of withholding enteral feeding, nasogastric decompression, IV fluids, hemodynamic support, administration of appropriate antibiotics, and surgical exploration if there is evidence of an acute abdomen with free air. Peritoneal drainage may be helpful for very-low-birth-weight babies and for those in extremis.[580] Total parenteral nutrition is frequently required for several weeks, and intestinal obstruction may occur weeks to months after a relatively benign course.[581]

Hepatic Failure. Hepatic failure occurs with chronic or acute liver disease. Chronic liver failure can be caused by biliary atresia, inborn errors of metabolism (tyrosinosis, Wilson disease, galactosemia, cystic fibrosis), or chronic inflammatory hepatitis. Children with chronic disease often have signs and symptoms of synthetic dysfunction (malnutrition, hypoalbuminemia, abnormal coagulation), degradation dysfunction (icterus and hyperammonemia), and portal hypertension (hypersplenism and varices). Acute liver failure is most commonly caused by infectious hepatitis A and B. Evidence of bleeding, edema, and other organ dysfunction, including identification of liver and spleen size, is sought on physical examination. Laboratory evaluation should include screening for synthetic function (albumin, prothrombin time [PT], partial thromboplastin time [PTT]), degradation products (bilirubin, ammonia), and liver enzyme concentrations. Hepatic ultrasound, radiographic contrast studies, and liver biopsy are indicated on an individual basis. Life-threatening complications of liver failure include acute bleeding and cardiovascular compromise (from massive intravascular hypovolemia as a result of fluid shifts) and intracranial hypertension from toxic encephalopathy. Treatment is expectant and supportive. A 10% dextrose infusion will provide adequate carbohydrate intake. Low-protein diets minimize ammonia production. Coagulation is supported with vitamin K, fresh frozen plasma, and platelets as required. Plasmapheresis with fresh frozen plasma and platelets improves coagulation and maintains normovolemia. Oral lactulose and neomycin enemas decrease the enterohepatic cycle of ammonia production and absorption.[582] Cardiovascular and respiratory function should be monitored closely and supported as required. The development of intracranial hypertension must be anticipated. Serum ammonia levels are used to monitor neurologic dysfunction,[582] but it is unknown whether ammonia is the primary CNS toxin or whether it is just one of many chemical markers. Steroids have been used for some forms of inflammatory hepatitis. Exchange transfusions and plasmapheresis have been used to decrease the toxin load,[583] but there is no strong evidence that such measures reduce morbidity and mortality.[584] Patients with certain forms of acute hepatic failure, including those resulting from toxic and infectious causes, may be considered candidates for liver transplantation.[228,585]

Extrahepatic Biliary Atresia. Extrahepatic biliary atresia occurs once in every 8000 to 10,000 live births.[586] The extent of atresia differs from patient to patient and involves variable degrees of obstruction or discontinuity of the biliary tree between the duodenum and the proximal branches of the hepatic ducts. Treatment is surgical (jejunal Roux-en-Y and portoenterostomy) and is tailored to the amount of extrahepatic bile duct present. The Kasai procedure is most successful in patients operated on before they are 6 to 9 months of age. However, this procedure is associated with many acute and chronic complications, including hepatic failure, ascending cholangitis, and cirrhosis with portal hypertension and varices. Despite these complications, the Kasai procedure persists because there are not enough suitable donor organs.[587]

Liver Transplants. Improved immunosuppressive drugs and surgical techniques have increased the success of liver transplantation (see Chapters 16, 60, and 61). For transplantation to be successful, the perioperative and postoperative periods require a coordinated approach among surgery, gastroenterology, anesthesia, immunology, and the ICU staff. Most of the clinical issues that arise can be anticipated. Large blood losses occur and massive replacement therapy is required in the operating room. Accordingly, intravascular volume status, renal status, and hematology/coagulation profiles must be closely monitored. The immunosuppression required puts the patient at risk for infection with both "normal" and opportunistic organisms. Surveillance cultures and early aggressive antibiotic therapy are indicated. Systemic hypertension, which appears to be unrelated to elevated CVP or pulmonary capillary wedge pressure, is due to the antirejection drugs. Many patients require aggressive antihypertensive therapy (hydralazine, diazoxide, captopril).[588,589]

Enteral and Parenteral Nutrition for the Critically Ill Child

Nutritional support of a patient in the PICU may be less of a concern to health care providers when there are neurologic, respiratory, and cardiovascular issues to be addressed. However, not addressing the nutritional needs of our patients misses an important opportunity to improve their care and outcome. The active area of research is to demonstrate the benefits of early enteral nutrition (EEN) in critically ill children. There are the potential benefits of reduced translocation of gut bacteria, reduced constipation, and reduced infectious risks as compared with parental nutrition. Research by Khorasani et al.[590] published in 2010 in a single center study showed decreased mortality in children with burns who received EEN 8.5% as compared with late enteral nutrition 12%. In a 2012 international multicenter cohort study published by Mehta et al.,[591] there was a lower 60-day mortality associated with a higher percentage of goal energy intake via an enteral route. The consecutively enrolled cohort consisted of 500 children ages 1 month to 18 years who required mechanical ventilation greater than 48 hours in a pediatric ICU. Their study further demonstrated that mortality was higher in the patients who received parenteral nutrition.[592] This research demonstrating EEN improves outcome in critically ill children is further supported by the 2013 work of Mikhailov et al.[592a] The study was a multicenter retrospective study with 12 participating centers. Pediatric patients 1 month to 18 years were included if they had a PICU length of stay ≥ 96 hours and a total of 5105 patients were identified. The study defined EEN as obtaining 25% of goal calories enterally within the first 48 hours of ICU admission. The study noted that children who received EEN were less likely to die as compared with those that did not (odds ratio, 0.51; 95% CI 0.34-0.76; $P = .001$). This was after adjusting for severity of illness, age, and participating center. There were nonsignificant increases in length of stay and duration of mechanical ventilation.

Given the increasing evidence supporting EEN, we should be considering daily whether it is possible to start feedings. We should also considering placing feedings tubes beyond the pylorus to that enteral nutrition can proceed during ICU procedures. Mehta et al.[592] showed significant interruptions in enteral feedings even after they had been initiated. Feeds were stopped on average for 2 days in 71% of their patients. If it is not possible for each of us to individually advance feedings, there is good information that adoption of a feeding protocol in an ICU setting increases goal enteral nutrition.[593] It is possible that between 25% and 30% of the patients admitted to the PICU are malnourished.[592] Smaller children and those with chronic illness have limited energy reserves, and early enteral feeding should be targeted. If enteral nutrition is not a possibility, parenteral should be considered, but it does carry risks. Higher dextrose solutions increase the risk of phlebitis or complications, should there be an infiltrate of a peripheral IV catheter. Higher dextrose concentrations might also require placement of central venous catheters, which carries risks during placement and ongoing risks of infection. Additional risks of parenteral nutrition include infection, cholestasis, hepatic stenosis, electrolyte disturbance, and elevated triglycerides. Until there is further evidence showing harm for malnourished children, initiation of parenteral nutrition should be considered if enteral feeding is not an option.

Hematology

Hematologic emergencies in the ICU include abnormalities in coagulation, immunity, and RBC mass. They can be primary isolated defects, or they can be caused by multiorgan system failure. The immune system is discussed in the section on infectious disease.

Coagulation System. Normal clotting includes initial platelet hemostatic plug formation and fibrin production (intrinsic or extrinsic pathways). For both to occur, platelets, coagulation factors, and an intact blood vessel are essential. Neonates have a number of measurable coagulation abnormalities that rarely have clinical manifestations. Full-term and most preterm infants have normal platelet-vessel interaction, but platelet aggregation is transiently impaired. In addition, many coagulation factors show decreased activity or concentration in the fetus and newborn. Of greatest importance are the vitamin K–dependent factors: factors II, VII, IX, and X. These factors are low at birth and decrease to even lower levels during the first week of life unless vitamin K is administered. The amounts of factor V and VIII are close to adult levels in all but the most premature of infants. Although routine screening tests for coagulation activity are prolonged in infants, the newborn's blood clots more rapidly in vitro because neonates lack sufficient naturally occurring protease inhibitors, principally antithrombin III.

Transfusion Therapy. Many PICU patients require blood transfusions during their hospitalization (Table 79.11). Decreased RBCs may be secondary to decreased production or ongoing losses frequent lab testing. Decreased platelets may be secondary to decreased production or sequestration in the spleen. Thrombocytopenia from frequent lab testing may be less common. Decreased production of coagulation factors in the setting of liver failure may predispose patients to further blood loss. The transfusion of blood products in any setting carries associated risks. Transfusion reactions can be separated into nonimmune and immune mediated problems. The nonimmune reactions include transmission of viral or bacterial infections through blood components, circulatory overload, coagulopathy, hypothermia, and changes in electrolytes. Hemolysis of erythrocytes in packed red blood cells (PRBC) is increased by prolonged storage. The potassium levels can be quite elevated in older units. In trauma or situations of acute blood loss, rapid transfusion of RBCs can lead to hyperkalemia. This is typically not a problem in an ICU setting, where PRBC are transfused over 2 to 4 hours. The immune mediated reactions include intravascular and extravascular hemolysis. Hemolytic transfusion reactions can be severe and life threatening. Cross-matching blood products can reduce hemolytic reactions, but there must also be careful identification of the patient and the blood unit to be transfused. Nonhemolytic immune-mediated reactions include febrile reactions, mild allergic, anaphylactic reactions, and transfusion-related acute lung injury (TRALI).

Transfusion Related Acute Lung Injury. TRALI previously may have been an under reported complication of transfusion, but awareness is improving. The number of studies on TRALI in pediatric ICU patients is increasing.[594-600] The diagnosis TRALI following a blood transfusion relies on excluding other causes of pulmonary edema. This includes eliminating volume overload, sepsis, and cardiogenic pulmonary edema as causes of the patient's pulmonary edema. It is proposed that there is a two-hit model of TRALI. The first hit is an underlying component of inflammation in the lungs. The second hit is transfusion of a blood product that results in the development of TRALI. It is still not clear whether the damage is caused by the presence of neutrophils, HLA antibodies, or biologically active lipids present in older blood units. A study by Church et al.[601] showed an association with increased mortality for pediatric patients with Acute Lung Injury who received fresh frozen plasma. Due to the ALI, this is a group that already has the first hit. The mortality association was independent of the severity of hypoxemia, the presence of disseminated intravascular coagulopathy, or the presence of multiple organ dysfunction syndrome. Blood transfusion has associated risk, and these risks should be considered prior to any transfusion. In some clinical scenarios, pediatric patients will tolerate a greater degree of anemia than we would have previously considered. In 2007 Lacroix et al.[602] with the Transfusion Requirements in Pediatric Intensive Care Units (TRIPICU) study demonstrated that by adopting a restrictive transfusion strategy, they were able to reduce transfusion of PRBCs to PICU. A hemoglobin threshold of 7 g was targeted in one group as compared with 10 g in other. In the restrictive threshold group, there was a 44% reduction in PRBC transfusion without an increase in adverse outcomes. This information may not be able to be applied to all groups in the ICU, such as those with ongoing blood loss. The patients in the TRIPICU study did not have a blood pressure lower than 2 SD below an age appropriate mean, and they did not require increasing doses of inotropic medication. Subgroup analysis of the original TRIPICU study in general pediatric surgery[603] and cardiac surgery patients did not show a significant difference in the development of multiple organ dysfunction syndrome.

TABLE 79.11 Blood Component Therapy

Blood Component	Dose	Comments
Packed red blood cells	10-20 mL/kg	Raises hemoglobin 2-4 g/dL
Random donor platelets	1 unit/10 kg or 5-10 mL/kg	Pooled units from multiple donors
Apheresis platelets	10 mL/kg	Donation from single donor
Fresh frozen plasma	10-20 mL/kg	Provides 20%-30% of coagulation factors
Cryoprecipitate	1 unit/10 kg	Significant amount of fibrinogen (50-80 mg/dL)

Coagulopathy. Coagulation defects can occur due to a number of underlying conditions in PICU patients, such as sepsis, trauma, malignancy, pancreatitis, and liver failure. As a reminder, the PT tests the extrinsic and common pathways of coagulation. The PT is prolonged in liver failure, vitamin K deficiency, and DIC. The activated partial thromboplastin time (aPTT) tests the intrinsic and common pathways of coagulation. The aPTT is prolonged in liver failure, hemophilia A, Von Willebrand disease, and DIC. One major concern in a PICU setting is that the underlying inflammatory state in some patients can activate coagulation and inhibit the natural anticoagulation mechanisms. This is the basis for disseminated intravascular coagulation. In 2001, the International Society of Thrombosis and Hemostasis[604] published a DIC scoring system. Their DIC score uses platelet count, fibrin-related markers, PT, and fibrinogen. They separated DIC into nonovert DIC and overt DIC. In nonovert DIC, the balance of hemostasis is stressed by inflammation or noninflammatory disorders of the microvasculature stress hemostasis, but compensation is maintained. In overt DIC, the hemostatic system is can no longer compensate. A DIC scoring system such as this allows for ongoing research and a measure of response to therapy. In 2009, Khemani et al.[605] demonstrated the association between an elevated DIC score and mortality in 132 PICU patients with sepsis or shock. There are a maximum of 8 total points on the DIC score. Lower platelet counts and fibrinogen, prolongation of the PT, and evidence of fibrin degradation all are given points. There was a 50% mortality for patients with overt DIC (DIC score ≥ 5). For patients with a DIC score of less than 5, the mortality was 20%. This association between elevated DIC score and mortality remained even when controlling for severity of illness and/or use of inotropic medications. The treatment of DIC is to treat the underlying condition which is causing imbalance of the coagulation system. A future goal of research will be to study patient outcomes as DIC is corrected with FFP. As Church et al.[601] found an increased mortality associated with FFP transfusion, it is not clear what the balance will be between the risk of DIC or the risk of transfusion.

Sickle Cell Disease. Hemoglobin S or sickle cell trait is the most common of the hemoglobinopathies. There are also significant regional variations on the concentration of patients with different thalassemias. Hemoglobin S is caused by a point mutation in the beta-chain at codon position 6, which results in a substitution of valine for the normal glutamine. Hemoglobin S is formed from the combination of an abnormal beta chains with the valine with normal alpha chains. When there are two copies of the abnormal gene present, hemoglobin SS or sickle cell disease is produced. Complications from sickle cell disease (Hb SS) cause the most frequent PICU admissions of the hemoglobinopathies. Deoxygenation of the Hb SS erythrocytes causes intracellular hemoglobin polymerization, which leads to loss of deformability and changes in the erythrocyte morphology. In a deoxygenated state the abnormal erythrocytes change from a biconcave configuration to the classic sickle cell shape. The abnormal erythrocytes have a much shorter life-span and hemolyze more readily. In turn, patients with sickle cell disease have a chronic severe hemolytic anemia.

Sickle Cell Crisis. There are three types of sickle cell crisis that can occur: hemolytic, aplastic, and vaso-occlusive. A hemolytic crisis is characterized by increased hemolysis, which results in an acute drop in hematocrit and hemoglobin. This is typically accompanied by a significant increase in red cell production or reticulocytosis. AI an aplastic crisis there is a drop in hematocrit and hemoglobin, but there is no associated reticulocytosis. The production of red cell precursors in the bone marrow has slowed or stopped. The cause of an aplastic crisis is often infectious with greater than 90% of cases due to parvovirus B19. A vascular occlusive crisis is what is typically thought of as the classic sickle cell crisis. A vascular occlusive crisis may be brought on by infection, dehydration acidosis, or hypoxia. The erythrocytes assume a sickled configuration, which blocks small vessels leading to infarction. The infarcts can occur in any organ but are frequent in the lungs, kidney, bones, skin, spleen, eyes, and CNS.

Acute Chest Syndrome. A vascular occlusive crisis in the lungs leads to acute chest syndrome (ACS). Acute chest syndrome is leading cause of death and the second most common complication in sickle cell disease. ACS is defined as a new pulmonary infiltrate on a chest radiograph, in association with a fever, respiratory symptoms, or chest pain. There is great variability to the clinical course in ACS. The National Acute Chest Syndrome Study Group[606] reported a multicenter showing almost 50% of patients later diagnosed with ACS present initially with another symptom, mostly typically being pain. The presence of a pulmonary fat embolism is frequently reported and is associated with a particularly severe course. The cause of the pulmonary fat embolism is most likely bone marrow necrosis with release necrotic bone marrow fat into the blood stream. A common etiology of ACS is infection. *Chlamydia pneumonia* and *mycoplasma* are the most commonly identified pathogens. The goal for management of ACS is early recognition. As children with sickle cell disease may have few initial symptom, there should be a high index of suspicion. All febrile children with sickle cell disease should have a chest radiograph obtained. If there is any positive radiologic findings, therapy should begin immediately. Initial antibiotic treatment is cefuroxime or cefotaxime with a macrolide. The patient should be adequately hydrated. The patient should be observed closely, and if the patient becomes fluid overloaded, diuretic therapy should be started. Patients should receive oxygen therapy even if there are normal oxygen saturations. Incentive spirometers should be used by every child who is able. There should be consideration given to the use of bronchodilators. Every effort should be made to see that pain is adequately controlled. A simple red cell transfusion may be helpful if the patient is anemic, but an exchange transfusion may be needed. There is some regional variation in this practice. The reason to perform an exchange transfusion is that as the hemoglobin rises the blood viscosity will increase. Further sickle cell blood has a very high viscosity in the deoxygenated state. Performing a red cell exchange can reduce blood viscosity as well as improve oxygenation.[604] An exchange transfusion may improve perfusion in the microvascular perfusion, as well as cause a reduction in inflammatory mediators. In patients with sickle cell disease, red cell exchange has been shown to reduce white blood count, platelet count, and soluble vascular cell adhesion molecule-1 in patients. However, there was no effect on interleukin-1α, interleukin-1β, interleukn-8, or tumor necrosis factor-α, and the reductions that occurred were short-lived. In the National Acute Chest Syndrome Study Group[607] publication, 13% of patients required mechanical ventilation, and in this group that required intubation, the mortality was 19%.

Neurologic Complications. Exchange transfusion has a vital role in the treatment of neurologic complications from sickle cell disease. In a population of patients with sickle cell disease, at less than 20 years of age the incidence of stroke was measured at 0.44 per 100 patient-years.[608] Studies have been performed to identify at risk patients and initiate therapy prior to the development of stroke. The Stroke Prevention Trial in Sickle Cell Anemia (STOP) was to evaluate whether chronic transfusion therapy could prevent an initial stroke in children with sickle cell disease. Transcranial Doppler was used to identify patients at increased risk for stroke. A hemoglobin S concentration of less than 30% was maintained in the study group.[609] The risk for stroke development was reduced by 90% in the chronic transfusion group, as compared with the patients receiving standard of care. The trial was stopped 16 months early due to these findings. Chronic transfusion therapy does carry the long-term side effects of alloimmunization and iron overload.[610] The information available would indicate that for a child with sickle cell disease and an acute neurologic change exchange transfusion should be performed. While there is a significant need with ACS or neurologic change, for an exchange transfusion, it is not without risks. Depending on regional variation, central venous or arterial access is needed. Patients need to be followed closely for the development of fluid overload or hypovolemia during the exchange. There are the risks of blood products. Small children are at risk for hypothermia if the blood is not warmed. The best location and method to handle exchange transfusion will depend on the resources of the ICU, blood bank, and hematology department.

Acquired Disorders. A variety of circumstances can impair the production of coagulation factors. The vitamin K–dependent factors are most commonly affected. These factors are decreased with liver disease, warfarin therapy, and malabsorption syndromes secondary to either bowel disease or altered bowel flora caused by long-term antibiotic therapy. In addition, untreated neonatal vitamin K deficiency results in hemorrhagic disease of the newborn. In these disorders, the PT is prolonged and there are low levels of factors II, VII, IX, and X. Administration of vitamin K usually reverses these deficiencies, unless the synthetic function of the liver is markedly compromised.

Acquired platelet abnormalities include decreased production, increased destruction, and decreased function. Decreased production or hypoproliferative states include marrow diseases, such as leukemia and aplastic anemia, and the side effects of chemotherapeutic agents. Increased destruction can be immune mediated (i.e., idiopathic thrombocytopenic purpura[611]) or the result of consumption (i.e., microangiopathic states, HUS, or thrombotic thrombocytopenic purpura[612]). Finally, platelet dysfunction has been found with uremia and chronic polycythemia in patients with cyanotic heart disease.[613] Treatment of acquired thrombocytopenia includes platelet transfusions and, if possible, correction of the underlying disorder. Therapeutic splenectomy will increase platelet survival in some patients with severe immune-mediated diseases.

Oncology

Over the past several decades, there has been significant improvement in survival of pediatric cancers. A great amount of information demonstrating this effect is available from the Surveillance, Epidemiology, and End Results Program at www.seer.cancer.gov. Further, there has been an increase in the number and types of diseases treated with hematopoietic stem cell transplantation (HSCT). These facts have resulted in an increasing volume of oncology patients in the pediatric ICU. This patient population received very specialized, detailed care on specialized oncology wards or bone marrow transplant units. The care delivered in these areas as well as the strict solation procedures employed there are difficult to replicate in other locations in the hospital. In an effort to keep oncology patients in oncology wards, some hospitals have policies allowing the use of low amounts of inotropic support in these areas—for example, dopamine up to 5 μg/kg/min. This may mean that some oncology patients are transferred to the ICU when they have exceeded this level of support. They may have sepsis and shock not responding to fluid resuscitation and low inotropic support. Other patients may require respiratory support that cannot be delivered on the ward. Finally, there is early literature indicating that earlier initiation of CRRT to treat or prevent fluid overload[614,615] has benefits in HSCT, with other studies showing no benefit.[616] However, the positive literature has prompted earlier admission to the ICU for HSCT patients who become fluid overloaded. Overall, there is evidence showing improved outcomes for pediatric oncology patients requiring ICU care.[617-620] For patients following HSCT, after controlling for severity of illness, a temporal improvement in mortality is less evident.[621] Further, for patients requiring mechanical ventilation, the mortality is greater following HSCT compared with non-HSCT oncology patients.[622]

Due to the disease and therapy at times during their illness, oncology patients are profoundly immunocompromised. There is an increased risk of sepsis during periods of neutropenia. Fever may be the first indication of sepsis and studies have looked at predicting which patients will go on to be bacteremic.[623,624] The outcome of sepsis and oncologic disease is an ongoing concern. A study by Pound et al.[617] showed that ICU mortality for patients with septic shock was not significantly different between oncology patients 15.9% compared with matched controls 11.6%. There was no significant survival difference between groups in the first 6 months following discharge from the ICU. A 2005 study by Fiser et al.[620] showed on overall mortality of 17% for pediatric oncology patients with severe sepsis. The mortality in the HSCT group (30%) was greater than the non-HSCT group (12%). For patients who required both mechanical ventilation and inotropic support there was a high mortality (64%).

Leukostasis

Leukostasis (vascular obstruction) results from high viscosity caused by elevated cell counts or by the WBCs themselves. This syndrome is anticipated in patients with acute lymphoblastic leukemia when the WBC count exceeds 500,000 and in AML patients with WBC counts greater than 200,000/mm^3. In AML, leukemic cells are less deformable than lymphoblasts, so a lower WBC count produces the same syndrome.

The brain and lungs are the two major target organs for leukostasis; vascular plugging and organ infarction are the usual manifestations. Initial symptoms include tachypnea, cyanosis, increased work of breathing, altered mental status, and focal neurologic deficits. Besides supportive therapy, reducing the circulating tumor load and viscosity are the primary goals of therapy. Leukapheresis and exchange transfusion transiently accomplish these goals. Cranial irradiation may reduce the CNS tumor load, and chemotherapy will interrupt cell production and possibly destroy circulating cells. The initial goal of chemotherapy is to stop cell production without producing massive cell lysis; this halts the increase in tumor load without causing a severe metabolic crisis before adequate perfusion is reestablished.[625,626]

Tumor Lysis Syndrome

TLS is a metabolic crisis precipitated by acute lysis of a large number of tumor cells. Serum uric acid, potassium, and phosphate concentrations are elevated; the elevated phosphate concentrations cause hypocalcemia. The hyperkalemia and hypocalcemia can be life threatening; increased uric acid may cause acute renal failure.[627] Therapy for TLS consists of alkalinization of urine, fluid administration, and diuresis. Before any chemotherapy is administered, the patient's renal function should be assessed. If renal function is normal, allopurinol or rasburicase therapy is begun. In most cases, this conservative approach of forced diuresis and allopurinol or rasburicase will prevent renal failure, but occasionally dialysis must be instituted. Indications for the initiation of dialysis include

1. Potassium greater than 6 mEq/L and rising despite resin exchange
2. Uric acid greater than 19 mg/L
3. Creatinine greater than 10 mg/L
4. Phosphorus greater than 10 mg/L or rapidly rising
5. Volume overload
6. Symptomatic hypocalcemia

Mediastinal Mass

Children with a mediastinal mass and respiratory distress often complain of coughing, difficulty breathing, stridor, and shortness of breath. They prefer to sit upright and cannot lie supine. The chest radiograph usually shows a large mediastinal mass, often with obliteration or obscuring of the tracheal air column. These masses can also cause positional obstruction of vascular structures such as the superior vena cava or a pulmonary artery. Lam et al. indicate that clinical presentation is often nonspecific or often times incidental, and that patients with airway compromise often times also exhibit symptoms of superior vena cava syndrome.[628] These patients are often referred to as having *critical mediastinal mass syndrome* and require the care of an experienced multidisciplinary team. These tumors can be malignant (87% Hodgkin and non-Hodgkin lymphoma) or benign; the prognosis and therapy rely on adequate diagnosis, which is best made by obtaining a tissue sample before treatment is begun.[629] However, obtaining a sample of the mediastinal mass may require anesthesia and surgery, and the airway must be manipulated and instrumented. All these maneuvers may cause the patient to die. Local anesthesia with fine-needle biopsy under radiographic guidance allows tissue sampling without anesthesia in some patients. Irradiation of the tumor before obtaining a tissue sample may reduce the size of the tumor and make biopsy easier and safer under anesthesia. Obstruction of the intrathoracic trachea is a major anesthetic risk for these patients; it is often impossible to maintain a patent airway when the patient lies supine, is deeply anesthetized, or is paralyzed with muscle relaxants.[628,630] However, the patient must cooperate sufficiently to perform the test, which is often difficult for them because of respiratory distress. Induction of anesthesia and tracheal intubation are usually done with the patient in the sitting position and breathing spontaneously. If the airway compromise is severe, the tumor should be irradiated and the child given steroids before a tissue diagnosis is made; however, these treatments could alter diagnosis and should be discussed with an oncology consultant prior to initiating. Sometimes, a peripheral node or mass can be biopsied under local anesthesia, or if the tumor mass is very large, some of the tumor can remain outside the field of radiation. Sticker et al. report that in a single center review of 46 cases that patients with symptomatic anterior mediastinal mass underwent biopsy with general anesthesia while maintaining spontaneous ventilation without serious complications.[630] In summary, although diagnosis is the key to treatment of neoplastic disease, the risk associated with biopsy may far outweigh the benefit of tissue diagnosis.

IMMUNITY AND INFECTION

Empiric Antibiotic Coverage

It is difficult to make empiric recommendations for antibiotic coverage for the pediatric ICU. Antibiotic resistance may result from use of broad spectrum antibiotics without some degree of stewardship. Further, empiric antibiotics should be based on the susceptibility profile of the common bacteria within each hospital and patient population. In our practice, for patients presenting with sepsis, vancomycin and a third generation cephalosporin in combination are the antibiotics of first choice. This is due to a rising incidence of methicillin-resistant Staphylococcus Aureus (MRSA). To reduce the spread of MRSA, all patients are screened on admission for colonization and isolated if MRSA is found. Antibiotic coverage can be more specific and narrowed as culture results as well as sensitivities return. Likely the best recommendation to be made regarding empiric antibiotic coverage is to meet with the Infectious Disease Specialists and discuss the current hospital culture isolates and their antibiotic resistance. Decisions regarding empiric antibiotics are best made in advance of the situation.

Prevention of Health Care–Associated Infections

The impact of health care–associated infections (HAI) on the medical system is significant and on the individual patient level can be deadly. A 2007 paper from Klevens et al.[631] estimated the number of HAIs in U.S. hospitals in the year 2002 at 1.7 million. Of these, 417,946 HAIs occurred among adults and children in an ICU setting. The estimated deaths associated with the HAIs in this time frame were 98,987. Likely the best thing we can do to protect our patients is to wash our hands or use alcohol-based gels and encourage others to do so. Encouraging others or providing a positive role model may have a larger impact than anticipated. A 2009 study by Schneider et al.[632] paired trainees who were critical care fellows or nurse orientees with senior supervisors and evaluated compliance with HH. In the control phase the senior supervisors were unaware of the study and had a HH compliance of 20%. The trainees that were being mentored had a HH compliance of 22%. When the senior supervisors were recruited into the study there was a HH compliance of 94%. The trainees who were still blinded to the study had an increase in the HH compliance to 56%. Certainly, it is anticipated that there will be better compliance with hand hygiene if health care providers know that they are being observed. Yet the Schneider study shows the importance of role modeling positive behavior. In our ICUs, we have ongoing audits of HH compliance. We ask our patients' parents to remind health care providers to wash their hands if they have not done so. Although it may be difficult, we must we willing to remind others to wash their hands.

Ventilator-Associated Pneumonia

Intubation and mechanical ventilation is necessary for patients with respiratory failure. Unfortunately, an ETT prevents airway protective mechanisms and this increases the risk of ventilator associated pneumonia (VAP). Patients mechanically ventilated who do not have a pulmonary infection may develop pneumonia and patients mechanically ventilated for pneumonia may develop a secondary infection. VAP can increase morbidity and mortality. A 2009 study by R. Srinivasan et al.[633] demonstrated that patients with VAP had increased length of mechanical ventilation, prolonged stays in the ICU, and more importantly a significant increase in mortality. There was 2.4% mortality in the patients who did not develop VAP as compared with 10.5% mortality in the patients who did. VAP has been defined as the new onset of a lower respiratory tract infection for patients who have required mechanical ventilation for greater than 48 hours. The diagnostic criteria includes a new infiltrate on chest radiograph, a positive respiratory culture, a low or elevated WBC count, and fever or instability in temperature.

In January 2005, the Institute for Healthcare Improvement (IHI) started the 100,000 lives campaign. The goal was to save the lives of 100,000 patients in a period of 18 months by six specific clinical interventions that were evidence based. They encouraged hospitals to deploy rapid response teams, deliver evidenced based care for acute myocardial infarction, prevent adverse drug events, prevent surgical site infections, prevent central line infections, and prevent VAPs. The last two incorporated the use of bundles or collections of scientifically grounded interventions that were implemented collectively. These interventions have been successful. From the VAP standpoint the pre-bundle VAP incidence for PICU patients was reported in 2002[634] as 11.6/1000 ventilator days. The VAP bundle has been tailored to pediatric patients,[635] and there have been significant improvements in VAP incidence. In a 2009 study showing the benefit of bundle implementation, Bigham et al.[636] showed a significant reduction in VAP incidence from 5.6 to 0.3 per 1000 ventilator days. This was a single center study that also showed a reduction in length of mechanical ventilation, length of stay, and mortality. This positive benefit of bundle initiation has been shown in other pediatric studies as well.[637,638]

In an effort to reduce a new bacterial infection while mechanically ventilated, the components of the VAP bundle aim to reduce bacterial colonization and prevent aspiration of contaminated secretions. To reduce the amount of bacteria present in the mouth and sinuses, mouth care is performed with a chlorhexidine rinse every two to four hours. Several things are done to reduce the risk of aspiration of contaminated secretions. One is to suction the oropharynx prior to suctioning the ETT or deflating the ETT cuff. A second is to drain the condensation that occurs in the ventilator tubing every two to four hours and prior to repositioning the patient. This should be done without disconnecting the ventilator circuit. A third is to use inline suction catheters such that the ETT can be suctioned without disconnecting the ventilator circuit. Finally, by maintaining the head of the bed greater than 30 degrees, there is a decreased risk of secretions in the ventilator tubing draining passively into the ETT.

We have found that the measures included in a VAP bundle are not difficult to perform and become routine practice quite quickly. More interesting is synergy that occurs with a bundle in that the impact of the combined interventions seems to be greater than any individual component. A strong adherence to a bundle of preventive measures has also been significantly helpful in the prevention of blood stream infection due to the presence of a central line.

Catheter-Associated Blood Stream Infections

There is a significant increase in hospital stay, morbidity, mortality, and costs with the development of catheter associated blood stream infections (CA-BSI). In a prospective study performed in a pediatric cardiac ICU Abou et al.[639] showed 11% mortality in patients who developed a blood stream infection as compared with 2% mortality in patients who did not. It has been said by many that the best way to reduce a CA-BSI is to never place a central venous catheter. There is benefit to continually reviewing a patient's requirements for central venous access and when possible only using peripheral catheters. Unfortunately, there are many instances such as the need for vasoactive medications, where central venous catheters cannot be avoided. The implementation of bundles to care for central venous catheters can significantly reduce the development of blood stream infections and reduce the mortality and morbidity for each patient.

Implementation of preventive bundles during the insertion of and ongoing maintenance of central venous catheters will reduce infections. In a 2010 study[640] in 29 PICUs, there was a 43% reduction in the development of CA-BSI when bundles were used. These results are sustainable and continue to improve. The 2011[641] follow-up by the same group showed a further reduction in the incidence of CA-BSI. The bundle can be broken down into two parts: central line insertion and maintenance. During the insertion of the central venous catheter the goal of the bundle is to maintain complete sterility of the field. Chlorhexidine is used as the skin prep for patients greater than 2 months of age. All people in the room wear hats and masks. The persons performing the procedure wear these as well, along with a sterile gown and gloves. A large sterile barrier covering the entire bed is used. The second phase of the bundle is ongoing maintenance of the central venous catheter. There are strict guidelines for the care of the IV tubing, hub, and catheter insertion site. When dressing changes are performed, sterile gloves are used and the area is scrubbed for 30 seconds with chlorhexidine; then it is allowed to air dry for 30 seconds. Strict adherence to the same maintenance guidelines throughout the entire hospital is necessary to prevent CA-BSI. In many institutions, the number of infections has dropped so low that each event can be individually reviewed.

Urinary Tract Infection

Catheter-associated urinary tract infections CA-UTI is the most common health care related infection. Removing a bladder catheter if it is not needed can significantly reduce the risk of developing a urinary tract infection. In some cases, the catheter cannot be removed and efforts should be made to prevent infection. Institution of a bladder care bundle as a quality improvement measure can significantly reduce infection rates. In a 2013 study by Esteban et al.,[642] implementation of quality improvement interventions decreased the number of catheter-associated urinary tract infections from 23.3 to 5.8 per 1000 urinary catheter days. The goals of a bladder catheter bundle are to reduce the bacterial colonization and to reduce the reflux of urine back into the bladder. Catheters are inserted in a sterile fashion, and periurethral cleaning is performed with a chlorhexidine cloth at least once per shift. To prevent reflux, the collection bag is always kept below the level of the bladder and is drained completely or clamped prior to moving the patient.

Infections in the Newborn

Neonates with developmental immunologic deficiencies have increased susceptibility to infection. Depressed cell-mediated immunity makes the fetus and infant more susceptible to viral and fungal infection. In addition, infants have depressed B-cell function and diminished production of immunoglobulins. The latter is partially offset by increased maternal immunoglobulin G (IgG). By 2 to 3 months of age, which is before infants can adequately produce their own antibodies in sufficient quantity, the level of maternal antibodies reaches a nadir.[643] The time during which the circulating antibody concentration is low is a time when the risk for infections is increased. Perinatal infections are either congenitally or postnatally acquired. Congenital infections occur with prenatal exposure to viral, protozoal, or rarely, bacterial pathogens. Common diseases include the TORCH infections: *Toxoplasma gondii* (T); “other” (O), including human immunodeficiency virus, syphilis, and tuberculosis; rubella (R); cytomegalovirus (C); and herpes simplex virus type 2 (H). Only rarely do these infections cause overwhelming sepsis, but they can be confused with bacterial infection when profound CNS depression, circulatory collapse, or thrombocytopenia occurs. When a TORCH infection develops in the first trimester of pregnancy, it causes fetal wastage or major organ malformation. Premature infants have a high incidence of acute infections in the newborn period. Regardless of gestational age, the signs and symptoms of infection are often subtle. Therefore, a very high index of suspicion and low threshold for diagnosing and treating infection are required.[644] Box 79.5 lists the common signs and symptoms of neonatal sepsis. The most common acquired pathogens are those that colonize the mother’s genital tract: group B streptococci, *E. coli*, *Listeria monocytogenes*, and herpesvirus. Herpes is such a fulminant infection in neonates that the presence of active herpes lesions in the birth canal is an indication for cesarean section, although this may not prevent herpes in all children. Group B *Streptococcus* is the most common bacterial pathogen that causes neonatal sepsis. Infection with group B streptococci is manifested as severe cardiorespiratory instability and meningitis in 30% of cases. By 2 to 3 weeks of age, this organism is more commonly associated with meningitis and less commonly with pulmonary disease. Whenever sepsis is suspected, cultures of blood, urine, and CSF should be obtained. Because it is difficult for the physician to localize the infection in an infant, repeated complete sepsis workups are often required. When appropriate cultures are obtained, treatment with ampicillin and an aminoglycoside, such as gentamicin, is usually begun until specific bacteriologic information becomes available. Only about 50% of neonates thought to be septic have positive cultures.

BOX 79.5 **Common Signs and Symptoms of Neonatal Sepsis**

Temperature instability (hypothermia and hyperthermia)
Lethargy and poor feeding
Respiratory distress and apnea
Hypoglycemia and metabolic acidosis
Poor cutaneous perfusion, hypotension
Rashes or petechiae
Seizures

PEDIATRIC TRAUMA

Prenatal and Perinatal Injuries

Perinatal trauma occurs before or immediately after birth (also see Chapter 77). The most common prenatal injuries are due to maternal gunshot wounds and blunt trauma. Fetal mortality in both cases is at least twice that of the mother,[645] with fetal death being attributable to maternal shock and fetal oxygen deprivation rather than direct injury. Birth injuries occur more commonly in large full-term infants and in infants born by breech presentation. Injuries to the head include linear or depressed skull fractures, cephalohematomas, subdural or subarachnoid hematomas, and intraparenchymal or intraventricular hemorrhage. Intracranial injuries can increase ICP and cause cerebral ischemia, neurologic injury, and death. Injury to the sternocleidomastoid muscle may cause torticollis; traction on the neck may transect the cervical spinal cord. Less devastating nerve 2 head injuries caused by cervical traction are phrenic nerve paralysis and Erb or Klumpke palsy, which are caused by brachial plexus stretching or tearing (or both). Shoulder dystocia is commonly associated with clavicular and humoral fractures; femoral shaft fractures occur with breech deliveries. Injuries to the liver, spleen, adrenal glands, and kidneys can cause life-threatening hemorrhage or thrombosis. Vasoocclusion causes tissue loss in the cerebral, coronary, or renal vascular beds. Emergency instrumentation of the airway in the delivery room on rare occasion leads to tracheal and esophageal perforation, particularly in a premature infant.

Trauma in Children

Accidents and trauma are the leading causes of death in children 1 to 14 years of age.[646] Children are frequently victims of falling or being dropped, drowning, near-drowning, motor vehicle accidents (pedestrian), ingestions, and burns. Head injuries are common, especially in younger children, who have disproportionately large heads and relatively poor neck muscle support.[647] Young children are less likely to be victims of gunshot or knife attacks; blunt injuries are more usual. Blunt trauma to the abdomen can cause solid organ injury (liver and spleen), rather than a perforated viscus. Hypothermia is a frequent complication of trauma; children lose heat rapidly because they have a relatively large surface-to-volume ratio. Drowning and near-drowning are the prototypical hypothermic injuries. Management of trauma patients of all ages requires an organized approach that permits rapid diagnosis and treatment. Most preventable deaths in pediatric trauma patients are caused by airway obstruction, pneumothorax, and shock; shock is often the result of inadequate treatment of bleeding or secondary brain injury from an expanding intracranial hematoma.[648] The American College of Surgeons recommends a four-step approach to pediatric trauma patients: (1) primary survey, (2) resuscitation, (3) secondary survey, and (4) definitive care.[271] The primary survey requires rapid assessment of the airway, breathing, and circulations. A disproportionately large tongue, in relation to a narrow oropharynx, easily obstructs the airway in an unconscious child. Proper jaw positioning enables bag-and-mask ventilation until the trachea is intubated. Ventilation through an inadequate airway may lead to gaseous distention of the stomach, vomiting, and aspiration of gastric contents. Cervical spine injuries are less common in children than in adults, but the child's neck should be immobilized until spinal injury is excluded. After establishing an airway, adequacy of respiration should be verified by observation of symmetric chest movement, auscultation of normal and equal breath sounds, and an early chest radiograph. Tension hemopneumothorax can be diagnosed clinically and treated by needle aspiration. Aspiration will alleviate the tension and stabilize the patient's condition until a chest tube can be inserted. Circulation can be quickly assessed by looking for tachycardia, poor peripheral perfusion, weak peripheral pulses, and hypotension (which may not occur until blood loss exceeds 25% of the circulating blood volume).[649] A severely hypovolemic child requires rapid insertion of a central venous catheter. If a peripheral venous catheter cannot be inserted expeditiously, an IO cannula should be placed.[650] The amount of volume resuscitation is dictated by the clinical condition of the child and the estimated volume of blood or plasma lost. During the secondary survey, a thorough head-to-toe examination is performed, and a plan of definitive treatment is developed. Diagnostic measures in a pediatric trauma patient are similar to those in adult patients, but there should be consideration of special problems that occur in children. Most intraabdominal injuries requiring laparotomy are recognized clinically because they produce peritonitis or cause increasing abdominal girth.[651] Diagnostic peritoneal lavage may be of help in children who are hemodynamically unstable, despite administering more than 40 mL/kg of blood. Peritoneal lavage may locate the site of occult bleeding in a child too unstable to undergo CT, or it can be used to evaluate abdominal injury in a child about to undergo emergency non-abdominal surgery. Many practitioners forego this procedure if surgery is imminent. Indications for surgical intervention for abdominal trauma include free peritoneal air, evidence of a ruptured viscus, and acute uncontrolled bleeding. A ruptured spleen or a liver laceration is not an indication for surgery in and of itself; the preferred treatment is supportive, blood volume replacement, and reevaluation.[652] A careful head and neurologic examination is done to quickly detect intracranial trauma. The most important indicator of intracranial trauma is a decrease in the level of consciousness. Rapid diagnosis and treatment of intracranial mass lesions will reduce ICP and may prevent secondary brain injury.

Child Abuse

The diagnosis of child abuse is made by finding an acute injury that may have a plausible explanation and signs of past trauma, including healing bruises, contusions, and fractures. Child abuse may also take the form of psychological or sexual abuse and failure to meet a child's need for food, clothing, shelter, hygiene, medical care, education, or supervision. Suspicion of child abuse begins with an inappropriate or inadequate explanation for the child's injuries or when the degree of trauma exceeds the stated cause. Multiple hospital admissions, emergency department visits, doctor or hospital "shopping," and a history of previous trauma should be of concern. Frequently, the story regarding the injury changes over time. Certain clinical features are common to child abuse, but they are by no means pathognomonic. Most abused children are older than 3 years and may have poor hygiene and delayed somatic or psychological development. The injuries most commonly include bruises, welts, lacerations, scalds, and burns from cigarettes, stoves, heating grates, or irons. Long-bone fractures, often of varying age, abdominal injuries, signs of smothering, and multiple soft tissue or genital bruises are also common. Head injuries can occur. Shaking an infant can cause neck injuries, intracranial hemorrhage, and contra-coup injuries, without necessarily producing external manifestations of trauma. The approach to a suspected victim of child abuse includes a meticulous and nonjudgmental history, written in detail in the chart. All allegations are recorded and changes in the reported history are documented. The physical examination includes growth parameters, descriptions of soft tissue bruising or burns, and diagrams or preferably photographs of all injuries. The color, shape, placement, and estimated age of all injuries should be catalogued. Laboratory studies should include the following: a skeletal survey of all long bones, ribs, and the skull; a coagulation profile, including hematocrit, platelet count, PT, and PTT; and genital and throat cultures for venereal disease if sexual abuse is suspected. If child abuse is suspected, it must be reported to the authorities.

Ingestion Injury

Despite the success of various preventive public health programs, poisoning continues to occur commonly in pediatric patients. Fortunately, the vast majority of presumed poisonings in young children can be managed by telephone consultation with a regional poison control center. In one study, acute poisoning accounted for approximately 5% of all medical admissions to a PICU.[653] Approximately half of these admissions were accidental ingestions, and half were attempted suicides. The median age for the accidental poisoning group was 2 years. For the suicide group, it was 15 years. Although many different toxic substances are ingested by children and adolescents, management of poisoning has three main goals: (1) identifying, decontaminating, and eliminating the toxic agents[654]; (2) minimizing the toxic effects on the child; and (3) providing close observation and organ system support until detoxification is complete. Procedures for drug elimination include emesis, gastric lavage, activated charcoal, and magnesium citrate.

Toxic effects can be minimized with specific antidotes when available, by hemodialysis, or by charcoal hemoperfusion. Examples of specific antidotes are deferoxamine for iron ingestion, ethanol infusion for methanol ingestion, naloxone for narcotic overdose, and *N*-acetylcysteine for acetaminophen ingestion. Because many ingestions, particularly those for attempted suicide, include multiple drugs, specific antidote therapy is only occasionally successful. Organ system support usually includes airway protection and mechanical ventilation, IV fluids, cardiovascular monitoring for arrhythmias and myocardial depression, and anticonvulsive therapy for patients who are seizing. Consultation with clinical pharmacologists or with the regional poison control center and contacting a social worker or psychiatrist are essential aspects of the care of an acutely toxic child. Common complications of ingestions and their therapy include aspiration pneumonia with hydrocarbon ingestion or loss of glottic function, sepsis, respiratory depression, myocardial depression, arrhythmias, seizures, and coma. The psychosocial environment that allowed or precipitated the ingestion must also be considered. Families should be counseled about proper supervision and "childproofing" their home. Psychiatric intervention should be introduced early; unsuccessful suicide attempts are often repeated.

Transport of the Critically Ill Child

Transport for critically ill children includes intrahospital and interhospital transport. Intrahospital transport of patients is necessary to and from the operating room. However, this also includes transport for radiologic procedures and studies throughout the hospital. In this circumstance, the clinician who ordered the test must understand the balance of risk and benefit. Is the information that can be obtained by an MRI worth the transport, changes in monitoring, and the time away from the ICU? In the case of a brain MRI, a patient may be away from the unit for 90 to 120 minutes with transport. There are significant differences in the ability to monitor and provide care to those patients. CT scans are certainly shorter but still entail many of the same risks. The severity of the patient's illness must be considered. Any patient with and ETT is at risk for obstruction or dislodgement. Any patient requiring inotropic support is at risk for those medications being interrupted. Depending on the hospital, the team transporting the patient may include a respiratory therapist, bedside nurse, and transport nurse. Some hospitals will send their ICU fellows, and some have a dedicated intrahospital transport team. When new equipment is purchased, transport monitors should be considered that have the ability to monitor end-tidal CO_2. In the smallest patients, the maintenance of body temperature can be difficult during transport.

Interhospital transport systems are typically set up by a tertiary care hospital. Smaller community hospitals may use outside resources. One should investigate the capabilities of the transport team available to you. Details to understand include availability of helicopter and fixed wing flight, types of practitioners on the transport team, coverage in the circumstance where the primary team is out on a transport, and the ability to provide interventions when the transport team arrives at the outside facility. Many transport care physicians will be able to intubate, place arterial and venous lines, and place chest tubes at an outside facility. All of this information is valuable when speaking to the referring hospital. In that regard, the person receiving the transport request may need to make some assessments of whether the patient is safe to transfer by a team that only provides basic life support resuscitation. For hospitals unfamiliar with caring for critically ill children, it may be foremost in their mind to get the child to a higher level of care and out of their hospital. They may not have taken into account what support is available during the transport if the patient deteriorates. They may be unwilling to wait for arrival of a transport team, but the overall needs of the child the focus of the discussion. When deciding on the make-up of the transport team, the distance of the referring hospital, condition of the child, ongoing resuscitation efforts, and chance of change in condition need to be taken into account. While the transport team is en route, the referring hospital should continue to support and resuscitate the child with advice from the receiving hospital. Further information regarding the development of a transport team is beyond the scope of this chapter. One excellent resource is the Guidelines for Air and Ground Transport of Neonatal and Pediatric Patients available through the American Academy of Pediatrics. An understanding of altitude physiology is necessary when considering transport by helicopter. One may not give much thought to the barometric pressure in the alveolar gas equation ($PAO_2 = (P_B - PH_2O)(FiO_2) - (PaCO_2/R)$). This is because at sea level P_B is 760 mm Hg. However, at 8000 feet P_B is 565 mm Hg. Supplemental oxygen may needed in flight, and for patients with significant lung disease, low saturation may remain even with supplemental oxygen. From Boyle's law ($\text{Pressure}_1 \times \text{Volume}_1 = \text{Pressure}_2 \times \text{Volume}_2$), there will be expansion of gas with the decreased pressure of altitude. This means that a small pneumothorax can expand to a large pneumothorax. The size of an ETT cuff can expand significantly, putting pressure on the trachea. The pediatric ICU relies significantly on the skills of our transport team. To maintain proficiency, the providers will need to practice intubation and other procedures. Please give some consideration to helping if you are asked to have a transport physician or nurse shadow you in the operating room to get some practice with intubation.

Acknowledgment

Portions of this chapter are taken from Dr. George Gregory's fine treatment of this topic in the last edition.
